Application of the Stokes equation requires certain assumptions that are not always achieved. All of these assumptions are critical to the measurement of the size of the sedimenting particles. The first assumption is that the particles are spherical, smooth, and rigid. Since this assumption is almost never valid, the diameter calculated is an equivalent or Stokes diameter (d_{St}). It is assumed that the particle terminal velocity is reached instantly, although calculations show that a finite but small time is actually required before this condition is reached. The particle is assumed to be moving without interference or interaction from other particles in the system. This assumption is only true at high dilutions (<1%) that ensure considerable separation between particles. Also, it is assumed that inertial effects are not present and that the fluid exhibits only Newtonian flow properties. Since water is generally the dilution medium in soils and colloidal particles are <1 μm, these assumptions are usually valid. A more detailed analysis of the methodology as well as a description of different centrifugation methods is provided by Bunville (1984), Groves (1984), Koehler et al. (1987), Holsworth et al. (1987), and Coll and Oppenheimer (1987).

15.1.3.1.4 Coulter Effect

The increase in the resistance across a small aperture produced by a nonconducting particle in a conducting medium is called the Coulter effect. The magnitude of this increase in resistance (ΔR) for a spherical particle of diameter (d_p) suspended in an aperture of diameter (D_a) is

$$\Delta R = \frac{8P_f d_p}{3\pi D_a^4}\left[1 + \frac{4}{5}\left(\frac{d_p}{D_a}\right)^2 + \frac{24}{35}\left(\frac{d_p}{D_a}\right) + \cdots\right] \qquad (15.3)$$

where P_f is the resistivity of the conducting medium. This resistance pulse (ΔR) results in a voltage pulse ($i\Delta R$) for a sphere

of diameter d_p, where i is the current across the aperture. The resulting voltage pulses are counted and scaled using a multichannel analyzer.

Instruments utilizing the resistive pulse technique require calibration using standard particles with known diameter to assign a particle size to each of the thresholds. This procedure takes into account the dimensions and electrical characteristics of the aperture and the conducting medium.

The advantage of the resistive pulse technique is that no other properties of the particle, such as refractive index or specific gravity, are required for the interpretation of the data in terms of a PSD. Developments in instrumentation for particle size analysis using the resistive pulse technique allow the analysis of particle sizes <1 µm but the range is limited (typically 0.4–<1 µm) (Bunville, 1984).

15.1.3.1.5 Dynamic Light Scattering or Photon Correlation Spectroscopy

Dynamic light scattering (DLS), also called photon correlation spectroscopy, or quasielastic light-scattering measures the fluctuation in scattered intensity of a laser beam over small-time intervals when it passes through a small volume of particles under Brownian motion. These fluctuations are dependent on the diffusion coefficient of the particles.

When the particles have a regular shape other than spherical, the depolarized component can be used to study the particle rotational diffusion coefficient. The rotational and translational diffusion coefficients obtained in conjunction with theoretical, hydrodynamic relationships contain information about the particle dimensions. For a nonspherical particle larger than the incident wavelength, light is scattered from different parts of the same particle producing interferences, which are dependent on the angle of the scattered intensity and characteristic of a particular particle shape (Pecora, 1983).

Limitations of DLS are due to the assumptions made in calculating the particle radius from the diffusion coefficients. These assumptions include sphericity, nonpenetrable spheres, and noncolumbic forces existing among the particles. A more major limitation, when applied to colloidal systems, is the strong particle size dependence of the scattered light intensity. Larger particles have a much larger influence than smaller particles, biasing size quantification toward larger particle sizes. Consequently, previous sample fractionation is advised, since small fractions of dust or other micrometer-sized particles will overshadow the signal of the particles in the colloidal range (Hassellov et al., 2008). Despite limitations, DLS is quick and easy to use, is available in most laboratories, and is very useful for monitoring changes in colloid aggregation. It has been applied successfully to measure particle sizes of colloids in natural systems (Rees, 1990; Ryan and Gschwend; 1990; Lebron et al., 1993; Ledin et al., 1993, 1994; Finsy, 1994; Perret et al., 1994; Newman et al., 1994; Filella et al., 1997).

15.1.3.1.6 Field-Flow Fractionation

FFF is a group of separation techniques capable of fractionating and characterizing the PSD of colloids in the range 0.01–1 µm.

Like chromatography, FFF is an elution methodology in which constituents are differentially retained, and thus separated in a flow channel (Beckett et al., 1997). With this technique, a colloidal sample is introduced into a stream of liquid and subjected to a field (such as gravitational, centrifugal, third cross-flow, thermal gradient, electrical, or magnetic) acting perpendicular to the stream direction (Beckett and Hart, 1993). According to theory, the rate at which particles are displaced downstream, measured as emergence times, can be related exactly to particle properties such as mass, size, and density. However, since different kinds of particles move at different velocities in this system, broad particle populations are sorted into graded size (or mass) distributions along the length of the flow channel. Observation of the shape of the emerging distribution, combined with theory, yields PSD curves called fractograms.

If applied as indicated above, FFF provides highly detailed size distribution curves and is a very flexible technique that can be adapted to different particle types in almost any suspending medium. The more commonly used FFFs in environmental applications are Sd-FFF and flow-FFF (Fl-FFF). Sd-FFF uses a centrifugal field to aid the separation of the colloids, while Fl-FFF uses a cross flow. For detailed information about FFF, Giddings (1993) provides a detailed explanation of this family of techniques and Hassellov et al. (2007) highlight the latest accomplishments of FFF for aquatic colloids and macromolecules.

Detection limits for colloid chemical analyses have been limited using traditional analytical techniques because the amount of colloids collected for analysis is generally limited. Presently, with the availability of low detection limit chemical analysis instrumentation such as graphite furnace atomic absorption spectrometer (GFAAS) and inductively coupled plasma-mass spectrometry (ICP-MS), concurrent particle size determination and chemical analyses can be conducted. Instruments can be assembled either off-line (disconnected) or online (connected) to achieve a more complete description of the colloid nature. Blo et al. (1995) used GFAAS as an off-line detector for Sd-FFF, while Contado et al. (1997) coupled online GFAAS to Sd-FFF to characterize suspended particulate matter from rivers. When analyzing colloidal fractions, techniques like inductively coupled optical emission spectrometry (ICP-OES) or ICP-MS that allow the simultaneous collection of multiple element signals are preferable. Sd-FFF was coupled with ICP-MS for the first time by Beckett (1991). Since then, many scientists have produced detailed chemical information about colloidal size fractions and associated elements (Murphy et al., 1993; Ranville et al., 1999). As per Table 15.3, Sd-FFF is only capable of separating particles down to ~50 nm. Since many colloids of interest are smaller, Chittleborough et al. (2004) developed the Fl-FFF-ICP-MS technique that can operate across the entire colloidal size range.

15.1.3.1.7 Acoustic Spectroscopy

Acoustic spectroscopy methods measure the propagation velocity and attenuation of sound waves (i.e., 1–100 MHz) passing through a colloidal suspension, providing information about the PSD, rheology, and electrokinetic behavior of the suspension.

Dukhin and Goetz (2002) provide a thorough discussion of acoustic methods and the six mechanisms of acoustic attenuation associated with a colloidal suspension: viscous, thermal, scattering, intrinsic, electrokinetic, and structural signal dissipation. The application of acoustic spectroscopy to colloid characterization assumes that each attenuation process functions independently and that the overall attenuation is the summation of the independent processes.

Viscous and thermal dissipation are the most important because colloids mainly interact with sound waves hydrodynamically through the generation of oscillating shear waves and thermodynamically through temperature losses. The resulting acoustic spectra are generally insensitive to the electrical conductivity of the solution and the charge of suspended particles and provide no information concerning particle morphology (Dukhin and Goetz, 2002; Seaman et al., 2003).

Acoustic attenuation attributed to the suspension is generally determined by measuring the relative change in signal at each frequency with precise changes in gap distance or sample path length in spectroscopic terms. Thermal losses dominate in emulsions and low-density dispersions, so that viscous losses may be neglected. For rigid submicron particles (i.e., soil clays, oxides), viscous attenuation dominates and limited information regarding composition of the particles (density), the media (solution density and shear viscosity), and the relative volume fraction of the two phases is required for estimating particle size, providing a minimum detectable particle size of approximately 10 nm. For complex environmental samples, however, such information may be lacking. Acoustic scattering becomes more important with increasing particle size, and sound speed must also be considered. When characterizing "soft" particles having a limited density contrast compared to the suspending solution, such as latex particles and polymers, additional information concerning their thermal expansion properties is required for interpretation of the attenuation spectra (Dukhin and Goetz, 1996, 1998, 2002).

Acoustic methods offer several advantages compared to other instrumental techniques for evaluating colloid size and surface charge properties. Ultrasound can propagate through suspensions to a much greater degree than light. Therefore, acoustic analysis can be conducted at relatively high solid to solution ratios (up to 30% solids by volume) that are more analogous to soil conditions in the field. However, the analysis may require more colloidal material than may be readily available. Analysis may be indicative of particle interaction within the intact suspension, lessening the impact of trace artifacts, that is, dust, bubbles, suspension heterogeneity due to particle segregation, and filtration artifacts that can bias sizing methods such as SEM and DLS. The applicable sizing range is much larger than light-scattering methods, that is, ≈5 nm–1000 μm. It is also less biased with respect to larger particles, making it more suitable for complex polydisperse systems. Acoustic methods are insensitive to sample convection, allowing stirring or agitation of the sample during analysis as required for reactive titration (e.g., Sun et al., 2006) or for the characterization of low charge,

inherently unstable suspensions, such as materials close to their zero point of charge (ZPC) and/or critical coagulation concentration (CCC) (Babick et al., 2000; Dukhin and Goetz, 2002; Kosmulski et al., 2002; Guerin and Seaman, 2004; Guerin et al., 2004; Delgado et al., 2005). Furthermore, the relatively large sample volume allows for the collection of subsamples throughout acoustic analysis for characterization by other analytical methods (Seaman et al., 2003).

Acoustic spectrometers for use in characterizing colloidal suspensions became commercially available in the 1990s. Despite several advantages when compared to light-scattering techniques, the application of acoustic-based methods to the study of soil colloids has generally been restricted to the characterization of mineral standards or synthesized mineral analogs, such as goethite and hematite (Gunnarsson et al., 2001; Kosmulski, 2002; Kosmulski et al., 2002, 2003; Appel et al., 2003; Guerin and Seaman, 2004; Guerin et al., 2004; Delgado et al., 2005). However, acoustic methods of suspension characterization rely on the interpretation of macroscopic sample properties, that is, the acoustic attenuation spectrum of a suspension, using idealized model algorithms with various simplifying assumptions and a few known system parameters, such as suspension concentration and particle density. The limited information can often result in systems that are "ill defined" and can be described by multiple answers, that is, PSDs (Dukhin and Goetz, 2001; Babick and Ripperger, 2002), a problem that also plagues light-scattering techniques (Schurtenberger and Newman, 1993). As such, acoustic methods are most suitable for evaluating relative changes in colloid aggregation and surface charge for suspensions in response to known changes in solution chemistry rather than for comparing subtle differences between poorly defined environmental samples.

15.1.3.1.8 Applications of Particle Size Methods

PSD is a fundamental soil property, affecting soil surface area, bulk density, porosity, water retention, and hydraulic behavior. Furthermore, precise information about colloidal size and shape is important because submicron-size colloids often act as vehicles that control the transport and fate of adsorbed pollutants (hydrophobic organic compounds, toxic trace metals, and radionuclides [de Jonge et al., 2004a]). Bacteria and viruses are part of the colloidal pool in natural environments; their characterization and transport are significant for understanding biogeochemical processes (Rockhold et al., 2004), epidemic evolution (Bertuzzo et al., 2008), and the spread of diseases in general (Khilar and Fogler, 1984; McDowell-Boyer et al., 1986; Kia et al., 1987; Ryan and Elimelech, 1996; Kretzschmar et al., 1999; de Jonge et al., 2004a; McCarthy and McKay, 2004; Tufenkji, 2007). Submicron-size colloids have been insufficiently studied in the past because methods for their isolation, detection, and characterization have been inadequate, with the exception of a few examples (Kaplan et al., 1993; Kretzschmar et al., 1993; Chanudet and Filella, 2006). However, with the new fractionation methods and the coupling with low detection limit analytical instruments (FFF-ICP-MS), a new era in the characterization of soil colloids

is commencing (Chittleborough et al., 2004; Ranville et al., 2005; Lead and Wilkinson, 2007).

Despite the new advances in the characterization and analysis of colloids, many unanswered questions exist in regard to in situ colloidal behavior in natural environments, in particular, the chemical nature of colloids present and their structure, size, and shape distributions (Filella et al., 1997; Lead and Wilkinson, 2007). New methods of in situ visualization of colloids in porous media are the research focus of several recent publications; light transmission and epifluorescent microscopy are some of the new techniques developed by Crist et al. (2004) and Baumann and Werth (2004) for the observation and modeling of colloidal transport in porous media.

15.1.3.2 Surface Area

Surface area must be regarded as a relative term, in as much as it is scale dependent, as well as often dependent on the chemical and physical conditions of a system. Determinations of surface area range from particle size calculations assuming smooth surfaces and simplified geometry, generally termed geometric surface area, to possible molecular level calculations based on the distances between surface ions in a mineral structure. Because the measurement is scale and system dependent, there is no universally accepted way to measure surface area. Determination as to which measurement system to utilize should consider the scale and chemical conditions required by the application. Kinetic reactions that are diffusion controlled should likely consider geometric surface area, while surface-controlled reactions (such as some adsorption and some dissolution/precipitation reactions) should consider surface area at the scale of the reacting molecule. In most instances, surface area is related to surface reactivity, either adsorption or surface-controlled kinetic processes.

15.1.3.2.1 Measurement Methodology

The results of surface area determinations must be interpreted within the context of the size and orientation of the adsorbate, as well as the attractive forces between the surface and the adsorbate. This distinction is particularly important for clays such as smectites, which can be considered to have internal as well as external surface area. Internal surface area is representative of the surface area of the interlayers. Inert gases such as N_2 are not able to enter the interlayer positions, and thus, measure only external surface area of clay particles. In contrast, polar molecules such as ethylene glycol, ethylene glycol monoethyl ether (EGME), and water are able to cause expansion of the layers and penetrate into interlayer positions. Use of such molecules results in measurement of internal and external surface area. Since water is the solvent in environmental systems, these total surface area measurements are appropriate for adsorption studies. Soil surface area measurements obtained using N_2, water, and EGME were highly correlated with each other and with clay content when considering soils with similar mineralogy but not for soils with differing mineralogy (de Jong, 1999).

To characterize adsorption methods of surface area determination, it is useful to distinguish between chemical and physical adsorption. Physical adsorption is characterized by low heats of adsorption without structural changes at the surface, fully reversible and rapid reactions since no activation energy is required, coverage of the entire surface rather than specific sites, little or no adsorption at elevated temperatures, and potential coverage by more than one layer of adsorbate (Lowell, 1979). Chemisorption is characterized by high heats of adsorption, localization of adsorption at specific surface sites, and irreversible reaction. The term "specific surface area" has been used to denote the surface area of a material expressed on a mass basis ($m^2 \ g^{-1}$).

15.1.3.2.2 Gas Adsorption Using the BET Equation

The BET equation is commonly used in conjunction with physical gas adsorption to measure surface area. The BET equation is named after Brunauer, Emmett, and Teller (1938), who extended the Langmuir theory for monolayer gas adsorption to multilayer adsorption. The Langmuir equation (Langmuir, 1918) is given by:

$$\frac{P}{V} = \frac{1}{kV_m} + \frac{P}{V_m} \tag{15.4}$$

where
  P is the pressure
  V is the volume of gas adsorbed per kilogram of adsorbent at that pressure
  k is a constant
  V_m is the volume of gas adsorbed per kilogram of adsorbent at monolayer surface coverage

The surface area is obtained by determination of $1/V_m$, which is the slope of the P/V versus P plot. The specific surface area is then equal to $1/V_m$ multiplied by the cross-sectional area of the adsorbate and the number of molecules in volume V_m.

The BET relation assumes that there is a dynamic equilibrium between the molecules in the various layers such that the number of molecules in each layer remains constant, although different sites may or may not be occupied at any given time. Use of the equation enables calculation of the number of molecules in a monolayer despite the fact that complete monolayer coverage may not have occurred. The BET equation is written as (Lowell, 1979):

$$\frac{1}{W[P_0/P]} = \frac{1}{W_m C} + \frac{C-1}{W_m C}\frac{P}{P_0} \tag{15.5}$$

where
  P is the adsorbate gas pressure
  P_0 is the adsorbate pressure at saturation for the temperature of the experiment
  W is the weight adsorbed in the monolayer
  W_m is the weight adsorbed in the complete monolayer
  C is the BET constant

Multipoint BET plots are created by plotting $1/(W(P_0/P - 1))$ on the y axis and P/P_0 on the x axis. The value of W_m is calculated from the slope and intercept. The specific surface area is determined by dividing the total surface area by the sample weight. The region of P/P_0 between 0.05 and 0.35 is usually linear and within the region of pressures corresponding to sufficient adsorption to complete monolayer coverage, and thus, best suited for determination of W_m (Lowell, 1979).

Often the BET surface area can be determined from a single pressure measurement without much loss of accuracy. For relatively high values of C, the intercept value is small relative to the slope and can be approximated by zero. The BET equation is thus reduced to (Lowell, 1979):

$$W_m = W\left(1 - \frac{P}{P_0}\right) \qquad (15.6)$$

Soil and mineral surface areas are most commonly measured by N_2 adsorption, using the BET equation. The calculation is made using the N_2 cross-sectional area of $0.162\,nm^2$ (Gregg and Sing, 1982). Often this area is referred to as the effective or occupied area. Alternatively for surface area $<1\,m^2\,g^{-1}$ the use of Kr is recommended.

Most commonly, the BET method consists of adsorption of N_2 at a fixed partial pressure P in a He–N_2 mixture and measurement of the desorbed N_2 in a pure He gas stream using gas chromatography. Alternative methods include measurement of the mass of N_2 adsorbed. In this method, the sample is evacuated to high vacuum, heated, then cooled to liquid N_2 temperature, and weighed. Quantities of N_2 are then added to the system and a series of weighings is made at various pressures. In this instance, the N_2 partial pressures are equal to the total pressure in the system.

Surface area can also be determined from the sorption of water at one or more vapor pressures (Newman, 1983). In this instance, air-dried samples are reacted in evacuated desiccators containing saline solutions with relative vapor pressures on the order of 0.2–0.4. Samples are equilibrated until there is no further weight change, then samples are dried at 105°C and weighed again. Sorbed water is taken as the difference between the oven-dry weight and the desiccator-equilibrated weight. Surface area is then calculated as with N_2, using Equation 15.5. This method gives values comparable to EGME values for nonexpanding clays but underestimates surface area for smectites due to limited water uptake in the interlayers (de Jong, 1999). For smectitic soils, de Jong (1999) recommended using the Langmuir equation (monolayer) for water sorption indicating that the reduced BET equation (Equation 15.6) is not applicable because interlayer water uptake is limited. de Jong (1999) demonstrated a correspondence close to 1:1 between surface area determined with EGME using the BET equation and with water using the Langmuir expression. It can be argued that water sorption values may be more realistic than EGME values (Pennell et al., 1995), since the interlayer spaces of smectites are not accessible to nonpolar molecules until at least two layers of water are present (Quirk and Murray, 1991).

15.1.3.2.3 Organic Molecules

15.1.3.2.3.1 Ethylene Glycol Ethylene glycol was utilized by Dyal and Hendricks (1950) for determination of total surface area of clays. The method consists of adding excess ethylene glycol to soil or clays and allowing the excess to evaporate under vacuum. It is assumed that when the rate of weight loss of the sample decreases, only a monolayer of ethylene glycol remains. Dyal and Hendricks (1950) calibrated the method assuming a bentonite surface area of $810\,m^2\,g^{-1}$ and calculated that 0.31 mg of adsorbed ethylene glycol corresponded to each square meter of surface area. The method was modified by Bower and Goertzen (1959) using $CaCl_2$-monoglycolate to maintain an ethylene glycol vapor pressure just below that of the saturation vapor pressure. In this method, the sample and the liquid are placed in separate open vessels in an evacuated system and the sample is weighed until it is in equilibrium with the vapor pressure of the ethylene glycol.

15.1.3.2.3.2 Ethylene Glycol Monoethyl Ether Ethylene glycol monoethyl ether (EGME) has replaced ethylene glycol as the polar solvent of choice for determination of surface area. Since EMGE has a higher vapor pressure than ethylene glycol, it requires a shorter reaction time to equilibrate the sample (Carter et al., 1986). A solvate of EGME and $CaCl_2$ is used in the evacuated chamber to lower the vapor pressure of EGME to just below the saturation pressure. Open vessels of EGME/$CaCl_2$ and soil are placed in the chamber and the soil is periodically weighed until no further weight gain is observed. It is assumed that the EGME surface coverage is $5.2 \times 10^{-19}\,m^2$ per molecule and that 0.286 mg adsorbed corresponds to $1\,m^2$ of surface area (Carter et al., 1986). The method is limited in that the EGME affinity for cations results in greater than monolayer coverage at those sites, the assumption that EGME covers all surfaces cannot be properly evaluated, and the large size of the molecule may prevent coverage in small surface voids. A serious reservation of the procedure is the assumption that the average EGME occupancy of smectite surface applies equally well to all soil surfaces, regardless of mineralogy (Tiller and Smith, 1990). These authors found that more EGME was retained per unit area by nonexpanding soil clays such as illites and kaolinites than by smectites resulting in an overestimation in surface area of 50%–100% when using smectite as a reference. Measurement of total surface area of soils with mixed mineralogy using EGME and a single conversion factor based on smectite leads to significant under- and overestimation of surface area of many soils, even including smectitic soils (Tiller and Smith, 1990).

15.1.3.2.3.3 Methylene Blue Methylene blue, an organic cation, is reacted at various concentrations with soil suspensions (typically with organic material removed) under pH-buffered conditions. Measurement of methylene blue concentration before and after reaction with soil is made spectrophotometrically at a wavelength of 665 nm. The adsorbed concentration of methylene

blue is used to calculate surface area assuming an area of 1.3 nm^2 per methylene blue molecule (Hang and Brindley, 1970). This surface area corresponds to the molecule attaching parallel to its long axis. This method can only be used in hydrated systems. Aringhieri et al. (1992) found surface areas determined with methylene blue to be unrealistically lower than those obtained with water adsorption and suggested that the major limitation of the method is its dependence on the soil surface charge characteristics. Alternatively, Borkovec et al. (1993) obtained relatively good agreement between methylene blue and N_2 BET surface areas for four soil samples assuming a methylene blue surface area of 0.247 nm^2, corresponding to a molecular attachment of methylene blue perpendicular to its long axis. Orientation of the organic molecules may be related to surface site characteristics, as well as concentration of adsorbing molecules. These differences illustrate one of the disadvantages of using charged molecules for surface area determination; their use is not recommended.

15.1.3.2.4 Electron Microscopy Image Analysis

Transmission electron microscopy as well as SEM can be used for determination of geometric surface area using a variety of methods, including calculation of planar surface area and assumptions regarding geometry to calculate total external surface area. With this method, only edge roughness can be measured. The SEM method, which offers the possibility of measuring the external surface roughness, consists of collecting two images at different sample tilt angles and constructing a three-dimensional representation of the surface. Surface area is calculated within a grid of fixed lines by summation of the planar surfaces in the grid. The ratio of the calculated surface to the area within the grid gives a measure of surface roughness. Measurements can also be made at different scales, providing information about the size distribution of the surface features. Since these measurements are typically made at the micrometer scale, and measure external surface area, it is not surprising that the values are intermediate between geometric surface areas based on particle size and BET values. Determination of specific surface area requires conversion of particle surface area to a mass basis using the particle density. The assumption that the particle density is equal to the density of specimen samples of the mineral is reasonable and introduces relatively minor errors in comparison to other assumptions made in the calculation. Increasing computer capacity and suitable software makes this method the most useful of the geometric methods.

15.1.3.2.5 Small Angle X-Ray Scattering

In this application, $K\alpha$ radiation from a conventional x-ray tube is scattered by freeze-dried samples in glass capillary tubes. The background-corrected x-ray-scattering intensity is plotted against the scattering vector (q) to obtain the apparent surface fractal dimension (D_s) using the relation (Borkovec et al., 1993):

$$I_q = Aq^{D_s-5} + B \tag{15.7}$$

where
  I_q is the scattering intensity
  A is a proportionality constant
  B is the background correction

Values of D_s obtained for soils using this method are in relatively good agreement with values calculated from gas adsorption surface area (a) for soil particle radii (r) using the relation (Borkovec et al., 1993):

$$a = C\lambda^{2-D_s} r^{D_s-3} \tag{15.8}$$

where
  λ is the size of the probing molecules
  C is the proportionality constant

15.1.3.2.6 Negative Adsorption

Negative adsorption refers to a deficiency in the concentration of an ion in solution adjacent to a solid surface relative to the concentration of the ion in the bulk solution. The deficit is caused by electrostatic repulsion between ions and surfaces of similar charge. Since most charged surfaces in soils are negatively charged, negative adsorption usually relates to solution anion concentrations and negative surfaces. For a 1:1 electrolyte, the diffuse double layer model produces the following approximation (Sposito, 1984):

$$d_e \approx \frac{2}{\sqrt{\beta c}} - \delta \tag{15.9}$$

where
  d_e is the exclusion distance
  c is the concentration of the bulk electrolyte
  β is a constant equal to $1.08 \times 10^{16} \text{ m mol}^{-1}$
  δ is the distance between two planes

The exclusion volume and area (S_e) are related by

$$V_e = S_e d_e \tag{15.10}$$

where V_e is the exclusion volume (the hypothetical volume from which the ion is completely excluded). Substituting into Equation 15.9 yields

$$V_e \approx \frac{2S_e}{\sqrt{\beta c}} - \delta S_e \tag{15.11}$$

The exclusion volume is calculated by first removing the bulk solution, determining the remaining liquid volume, displacing the liquid, and analyzing for the bulk solution and extract concentration. The exclusion volume is then equal to the mass deficit in the extract divided by the concentration in the bulk solution.

A plot of V_e vs. $c^{-0.5}$ should yield a straight line whose slope is proportional to the exclusion specific surface area as shown by inspection of Equation 15.11.

This method was first described by Schofield (1949), who used it to determine montmorillonite surface area from reactions with NaCl, NaNO$_3$, and Na$_2$SO$_4$ solutions. Subsequent work by Edwards et al. (1965a, 1965b) demonstrated that the specific surface area determined with this method varied with cation selected. Calculated values for illites ranged from values close to the N$_2$ BET values with Li to 0 with Cs. In contrast, for montmorillonite, LiCl exclusion volumes were 10 times greater than N$_2$ BET surface areas, while Cs values were comparable to those obtained by N$_2$ BET. Trends in surface area values measured using anion exclusion for Li, Na, K, NH$_4$, Cs, and Ca-montmorillonites were in agreement with those calculated from a tactoid model (Schramm and Kwak, 1982a, 1982b).

15.1.3.2.7 Applications

Surface area measurements are required for a variety of calculations. In most soils, the bulk soil surface area is dominated by the surface area of the clay minerals. Surface charge density, which requires measurement of both surface area and particle charge, has been related to cation exchange selectivity. As expected, increasing surface charge density favors adsorption of the higher valence cation in heterovalent exchange (Maes and Cremers, 1977). Surface charge density is also required for calculation of double layer thickness and for use in a variety of adsorption relationships. Determination of specific surface area is required for chemical studies on many different minerals. In this case, bulk surface area is not appropriate. Controlled laboratory studies are often performed using addition of quantities of a well-characterized mineral having a known surface area. This method is used to study a variety of chemical reactions, such as kinetics of calcite, gypsum, and dolomite dissolution, surface area of calcite for prediction of phosphate adsorption, and addition of various Fe or Mn oxides for study of adsorption and redox processes. Among the various applications of the EGME method, Ross (1978) related shrink/swell properties of soils to surface area and Supak et al. (1978) related the specific surface area of clays to the adsorption of the pesticide aldicarb.

15.1.3.3 Surface Charge

The total net surface charge on a particle (Φ_p) is

$$\sigma_p = \sigma_s + \sigma_H + \sigma_{is} = \sigma_{os} - \sigma_d \tag{15.12}$$

where

σ_s is the permanent structural charge

σ_H is the proton surface charge resulting from the specific adsorption of protons and hydroxyl ions

σ_{is} is the inner-sphere complex charge resulting from specific ion adsorption

σ_{os} is the outer-sphere complex charge resulting from non-specific adsorption

σ_d is the dissociated charge

This definition is similar to the one provided by Sposito (1984) with the exception that total net surface charge results from isomorphic substitution and is generated by specifically adsorbing ions (Hunter, 1981). An inner-sphere surface complex contains no water between the adsorbing ion and the surface functional group; while an outer-sphere surface complex contains at least one water molecule between the adsorbing ion and the surface functional group (Sposito, 1984). Examples of surface functional groups are reactive surface hydroxyl groups on oxide minerals, aluminol and silanol groups on clay minerals, and carboxyl and phenol groups on SOM.

15.1.3.3.1 Measurement Methodology

The total net surface charge can be measured directly using electrokinetic experiments. The point of zero charge (p.z.c.) of a particle is the solution pH value where total net particle charge is zero. The p.z.c. can be measured directly using electrokinetic experiments or indirectly from potentiometric titrations under certain experimental conditions (Sposito, 1984).

Electrokinetic phenomena are processes where a relative velocity exists between two parts of the electrical double layer (Hiemenz, 1977; Hiemenz and Rajagopalan, 1997). In this motion, a thin layer of liquid remains with the solid and a shear plane is located between the solid and liquid phases at some distance from the solid surface (van Olphen, 1977). The electric double layer potential at the shear plane is called the zeta potential (ζ). The assumption that ζ is equal to or very close to the diffuse double layer potential (ψ_d) is supported indirectly by a large body of data on a variety of surfaces (Hunter, 1981, 1989). The principle electrokinetic phenomena that measure zeta potential are discussed later.

15.1.3.3.2 Electrophoresis

Electrophoresis measures the movement of a suspended charged particle in response to an applied electric field. This movement is called electrophoretic mobility (μ_E) and is given by the Smoluchowski equation (Hunter, 1989):

$$\mu_E = \frac{\varepsilon \zeta}{\eta} \tag{15.13}$$

where

ε is the relative permittivity

η is the viscosity

The Smoluchowski equation applies when the particle dimensions are much greater than the double layer thickness (Hunter, 1987). The complete formula relating ζ and μ_E is derived by the theoretical evaluation of the electric force on the charged particle (f_1), the hydrodynamic frictional force on the particle by the liquid (f_2), the electrophoretic retardation force (f_3), a frictional force resulting from the movement of water with the counterions, and the relaxation force (f_4), caused by distortion of the double layer around the particle (van Olphen, 1977). Additional considerations arise

for nonspherical particles and those carrying two double layers such as clays. For these reasons, the Smoluchowski equation is, in general, only approximate and it is advisable to report electrophoresis results as electrophoretic mobility rather than to attempt to convert to zeta potential (van Olphen, 1977).

Electrophoresis is the most common method of determining zeta potential. For colloidal systems, the most appropriate technique is microelectrophoresis where the movement of individual particles is followed directly by microscopy (Hunter, 1981). Microelectrophoresis is only applicable at very low particle concentrations. Electrophoresis can also be studied using laser Doppler velocimetry and photon correlation spectroscopy. The mass transport mobility apparatus measures electrophoretic mobility from the mass of colloids transported to a suitable electrode compartment (Hunter, 1981). This apparatus can be used at much higher particle concentrations than microelectrophoresis.

15.1.3.3.3 Electroosmosis

Electroosmosis measures the movement of the liquid adjacent to a flat, charged surface in response to an electric field applied parallel to the surface. This movement is called electroosmotic velocity (v_{eo}) and is also obtained from the Smoluchowski equation (Hunter, 1987):

$$v_{eo} = \frac{-\varepsilon \zeta E}{\eta} \qquad (15.14)$$

where E is the electric field strength. While it is possible to measure electroosmotic velocity directly using microscopy, it is more common to measure the volume of liquid transported per unit time (Hunter, 1981):

$$\frac{V}{i} = \frac{\varepsilon \zeta}{\eta \lambda_0} \qquad (15.15)$$

where

    V is volume
    i is the electric current
    λ_0 is the electrical conductivity

The material whose zeta potential is being measured is formed into a porous plug and the transport of liquid across a tube in response to an electric field may be obtained by measuring the movement of an air bubble in the capillary providing the return path (Adamson, 1976). It is also possible to measure the electroosmotic flow by applying a counter pressure until the flow is exactly compensated (Hunter, 1981).

15.1.3.3.4 Electroacoustic Spectroscopy

A general discussion of the application of acoustic spectroscopy for characterizing colloidal suspensions was presented earlier in this chapter (Section 15.1.3.1). Both acoustic and electroacoustic spectrometers are commercially available separately or combined in a single instrument. In electroacoustic spectroscopy,

one measures either (1) the colloid vibration potential (CVP) or colloid vibration current (CVI), the induced dipole moment created by the displacement or polarization of the electrical double layer in response to an acoustic wave, or (2) the electrokinetic sonic amplitude (ESA) generated by the movement of a charged particle in response to an electrical field as indicators of colloidal zeta potential. The individual dipole moments created by the interaction of sound waves with a colloidal suspension can be measured as an alternating electrical field that varies with the amplitude of the sound wave. Conversely, the electrophoretic movement of charged particles in response to an applied electrical field gives rise to sound waves, known as the ESA effect. Although electroacoustic spectroscopy can provide PSD, such information is best derived from the conventional acoustic spectra (Dukhin and Goetz, 2002; Seaman et al., 2003).

In contrast to microelectrophoretic light-scattering methods, electroacoustic measurement of zeta potential can be conducted at much higher suspension concentrations (30%–50% solids), an obvious advantage given that sample dilution and changes in solution chemistry can impact the expression of zeta potential and apparent particle size (Dukhin et al., 2001; Dukhin and Goetz, 2002; Delgado et al., 2005). Acoustic methods have been used to evaluate shifts in the isoelectric point (IEP) of materials at high-ionic strengths as indicators of specific and nonspecific sorption mechanisms (Kosmulski, 2002; Kosmulski et al., 2002; Greenwood, 2003). Such applications are best used in combination with other surface active spectroscopic methods for determining sorption mechanisms. In comparing various techniques for evaluating the IEP and p.z.c. of Fe (hydr)oxides, Kosmulski et al. (2003) noted that electroacoustic methods produced higher IEP values than observed for potentiometric titration methods. The cause of the discrepancy was not discussed.

15.1.3.3.5 Streaming Potential

The streaming potential is an electric potential difference generated when liquid adjacent to a charged surface is set in motion by an applied pressure gradient (Hunter, 1987). The streaming potential (Φ_{st}) is also governed by the Smoluchowski equation and given by (Sposito, 1984)

$$\Phi_{st} = \frac{\varepsilon \zeta}{\lambda_0 \eta} \Delta P \qquad (15.16)$$

where ΔP is the applied pressure difference. The streaming potential can be measured in similar fashion as the electroosmotic velocity. Liquid is forced under pressure through a porous plug and Φ_{st} is measured by electrodes in the solution on either end (Adamson, 1976).

15.1.3.3.6 Sedimentation Potential

When particles having charged surfaces settle in a liquid under the force of gravity, a plane of shear is developed. As the particles settle, the interfacial charge is separated since a portion inside the shear plane moves with the particle and the remainder is left behind (Sposito, 1984). An electric potential difference arises

from the separation of charge called the sedimentation potential. The gradient for the sedimentation potential, $d\Phi_{sed}$, is given by (Sposito, 1984)

$$\frac{d\Phi_{sed}}{dz} = \frac{\varepsilon\zeta}{\lambda_0\eta}n\Delta\rho g \qquad (15.17)$$

where
   n is the number of particles per unit volume
   $\Delta\rho$ is the difference in mass density between the particles and the liquid phase
   g is gravitational acceleration
   z is distance

The potential difference is measured by inserting reversible electrode probes at two different heights in the column of settling particles (Hunter, 1981). For low particle concentration, the sedimentation potential is also governed by the Smoluchowski equation (Hunter, 1981).

15.1.3.3.7 Potentiometric Titration

Potentiometric titration measures the surface density of proton surface charge (σ_H) defined as (Sposito, 1984)

$$\sigma_H = \frac{F}{A}(q_H - q_{OH}) \qquad (15.18)$$

where
   F is the Faraday constant
   A is the specific surface area
   q_H is the complexed proton charge (mol)
   q_{OH} is the complexed hydroxyl charge (mol) per unit mass of solid

Titration data consist of pH readings obtained while known amounts of acid or base are added to a solid suspension. A net titration curve is obtained by subtracting a calibration curve obtained by titrating the equivalent supernatant solution. The values of $q_H - q_{OH}$ are given by (Sposito, 1984)

$$q_H - q_{OH} = \frac{C_A - C_B - [H^+] + [OH^-]}{C_s} \qquad (15.19)$$

where
   C_A is the molar concentration of acid added
   C_B is the molar concentration of base added
   $[H^+]$ is the molar proton concentration
   $[OH^-]$ is the molar hydroxyl concentration obtained from pH measurement
   C_s is the particle concentration

In order for Equation 15.19 to be valid, added protons and hydroxyl ions must only react with surface-reactive functional groups whose charge is pH dependent. Usually, other reactions that are also pH dependent occur, such as soluble complex formation, dissolution of solid phases, or complexation with surfaces whose charge is not pH dependent (Parker et al., 1979). Without these corrections, no surface chemical significance can be provided by Equation 15.19. A detailed description of the use of potentiometric titration to determine surface charge is provided by Huang (1981).

15.1.3.3.8 Applications

One of the most important applications of electrokinetic experiments and potentiometric titrations is the determination of the p.z.c. A characteristic of variable charge minerals is the p.z.c. obtained in the presence of an inert electrolyte. This p.z.c. is determined electrokinetically as the pH value where the zeta potential is zero or indirectly from the point of zero net proton charge (p.z.n.p.c.) or from the point of zero salt effect (p.z.s.e.) obtained potentiometrically. The p.z.n.p.c. and the p.z.s.e. are discussed in detail in Chapter 16. The p.z.n.p.c. and the p.z.s.e. are equivalent to the p.z.c. in the absence of surface complex formation. Table 15.4 provides characteristic values of p.z.c. obtained using electrokinetic experiments and potentiometric titrations for a variety of variable charge minerals.

TABLE 15.4   Representative Points of Zero Charge for Various Minerals

Solid	p.z.c.
Electrophoresis	
Goethite	8.8
Hematite	8.5
Magnetite	6.9
Amorphous iron oxide	8.0
Gibbsite	9.8
Bayerite	9.2

FIGURE 15.2 Relation between zeta potential and dispersible clay of Na-clay minerals obtained using electrophoresis. (Reprinted from Chorom, M., and P. Rengasamy. 1995. Dispersion and zeta potential of pure clays as related to net particle charge under varying pH, electrolyte concentration and cation type. Eur. J. Soil Sci. 46:657–665. With permission of Blackwell Science Ltd.)

Electrokinetic experiments and potentiometric titrations can be used to infer adsorption mechanisms for adsorbing ions on surfaces. Adsorption of ions that form inner-sphere surface complexes is characterized by shifts in the p.z.c. of the particles and reversals of their electrophoretic mobility with increasing ion concentration (Hunter, 1981). Adsorption of ions that form outer-sphere surface complexes does not produce p.z.c. shifts since they are assumed to lie outside the shear plane. Figure 15.1 presents the shifts in p.z.c. and charge reversals observed for gibbsite upon the specific adsorption of increasing amounts of molybdate. These results are indirect evidence for inner-sphere surface complexation of this ion.

Net particle surface charge is a primary factor in dispersion of clay minerals. Zeta potential as a measure of particle surface charge was also related to percentage of dispersible clay (Chorom and Rengasamy, 1995). Figure 15.2 indicates the relationship between zeta potential measured using electrophoresis, and dispersible clay for Na-saturated kaolinite, montmorillonite, and illite.

The plane interface technique determines the electroosmotic velocity at large plane interfaces and can be used to determine the zeta potential of two different surfaces at the same time under the same conditions (Nishimura et al., 1992). These authors used the plane interface technique to simultaneously study silica plates and muscovite mica basal planes. The zeta potential values for silica presented in Figure 15.3 indicate that the asymmetric silica–mica cell provides results comparable to those of the symmetrical silica–silica cell.

Zeta potentials of clay minerals have also been determined using a flat plate streaming potential apparatus for muscovite mica (Scales et al., 1990), saponite, and hectorite (Nishimura et al., 2002a). Zeta potential of clays becomes less negative with increasing electrolyte concentration as a result of double layer compression (Figure 15.4). The resulting charge reduction causes clay flocculation. Streaming potential measurements of sodium montmorillonite using a flexible wall permeameter were
FIGURE 15.3 Zeta potentials as a function of solution pH for muscovite mica basal plane– and silica plate–aqueous solution interfaces obtained using electroosmosis. (Reprinted from Nishimura, S., H. Tateyama, K. Tsunematsu, and K. Jinnai. 1992. Zeta potential measurement of muscovite mica basal plane-aqueous solution interface by means of plane interface technique. J. Colloid Interface Sci. 152:359–367. With permission of Academic Press, Inc.)

found to be dependent on the salt concentration of the permeating solution (Heister et al., 2005).

A vastly different application of electrokinetic experiments is the application to dewatering and decontamination of soils
FIGURE 15.4 Relation between zeta potential and electrolyte concentration for various 1:1 electrolytes obtained from streaming potential. (Reprinted with permission from Scales, P.J., F. Grieser, and T.W. Healy. 1990. Electrokinetics of the muscovite mica–aqueous solution interface. Langmuir 6:582–589. Copyright 1990 American Chemical Society.)

and clays. For example, electroosmosis has been used for removing organic contaminants from kaolinite and soil clays (Shapiro and Probstein, 1993; Schultz, 1997; Kim et al., 2001). These authors present applications for in situ hazardous waste remediation of soils. Economic analysis indicated that electro-osmosis compared favorably with the cost of excavation and ex situ treatment (Schultz, 1997).

A potentiometric titration method has been developed to account for changes in solubility of the solid with changes in pH (Schulthess and Sparks, 1986). This is a batch method where the reference for each sample is the supernatant specific to that sample back titrated to pH 7. This method is considered to account for all sources of proton consumption (Schulthess and Sparks, 1986).

15.1.4 Thermodynamics of Colloid Surfaces

To develop the thermodynamic treatment of the surface region, a few definitions are useful. The interfacial region is a space between two adjoining phases (gas–liquid, gas–solid, liquid–liquid, liquid–solid, solid–solid), which is characterized by inhomogeneity in its properties. The Gibbs surface is a mathematical dividing surface, without volume, drawn parallel to the boundaries of the interfacial region, which is used to define the volumes of the two adjoining bulk phases. A schematic of the interfacial region and the Gibbs surface is presented in Figure 15.5. The actual values for the system as a whole will differ from the sum of the values for the bulk phases by an excess or deficiency due to the Gibbs surface (Adamson, 1976). The following relations hold for the variables of state:
FIGURE 15.5 Representation of the interfacial region and the Gibbs surface.

$$\begin{aligned} \textit{Volume}: &\quad V = V^{\alpha} - V^{\beta} \\ \textit{Internal Energy}: &\quad E = E^{\alpha} + E^{\beta} + E^{\sigma} \\ \textit{Entropy}: &\quad S = S^{\alpha} + S^{\beta} + S^{\sigma} \\ \textit{Moles}: &\quad n_i = n_i^{\alpha} + n_i^{\beta} + n_i^{\sigma} \end{aligned} \qquad (15.20)$$

where
   α and β denote the bulk phases
   σ denotes the Gibbs surface (Adamson, 1976)

Additional variables of state are defined as the surface tension or surface free energy (γ) and the area of the Gibbs surface (A).

The three fundamental thermodynamic relationships of surface chemistry are the Young–Laplace equation, the Kelvin equation, and the Gibbs equation (Adamson, 1976). The Young–Laplace equation is the fundamental equation of capillarity for a curved Gibbs surface:

$$P^{\beta} - P^{\alpha} = \gamma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \qquad (15.21)$$

where
   $P^{\beta} - P^{\alpha}$ is the capillary pressure
   r_1 and r_2 are the radii of curvature

The Kelvin equation gives the effect of surface curvature on the molar free energy of a substance. The free energy of a substance can be related to its vapor pressure assuming the vapor to be ideal (Adamson, 1976). The Kelvin equation is

$$\ln \left(\frac{P}{P_0} \right) = \frac{\gamma V}{RT} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \qquad (15.22)$$

where
   P_0 is the normal vapor pressure of the liquid
   P is the vapor pressure observed over the curved surface
   R is the molar gas constant
   T is temperature

For a small, reversible change dE in the energy of the system (Adamson, 1976)

$$dE = dE^\alpha + dE^\beta + dE^\sigma$$

$$= TdS^\alpha + \sum \mu_i dn_i{}^\alpha - P^\alpha dV^\alpha + TdS^\beta$$

$$+ \sum \mu_i dn_i{}^\beta - P^\beta dV^\beta + TdS^\sigma + \sum \mu_i dn_i{}^\sigma - P^\sigma dV^\sigma + \gamma dA$$

$$(15.23)$$

where μ_i is chemical potential. Substituting for dE^α and dE^β and manipulating the equation for dE^σ lead to the expression (Adamson, 1976)

$$S^\alpha dT = Ad\gamma + \sum n_i{}^\sigma d\mu_i = 0 \qquad (15.24)$$

At constant T and A, the Gibbs equation is

$$-d\gamma = \sum \frac{n_i{}^\sigma}{A} d\mu_i = \sum \Gamma_i{}^\sigma d\mu_i \qquad (15.25)$$

where $\Gamma_i{}^\sigma$ is a surface excess concentration per unit area defined as $\Gamma_i{}^\sigma = n_i{}^\sigma/A$. The Gibbs equation can be applied to liquid–liquid and liquid–vapor interfaces where the surface tension can be measured to calculate the surface concentration of the adsorbed species causing the surface tension change. Similarly, if the surface concentration can be measured directly but the surface tension cannot, the Gibbs equation can be used to calculate the lowering of γ from the measured adsorption in solid–gas and solid–liquid systems (Hunter, 1987).

15.2 Interparticle Forces

15.2.1 Electrical Double Layer

Double layer theory describes the distribution of ionic concentrations near electrostatically charged particles. The charge on the colloidal particles is due to isomorphic substitution in the particle lattices or arises from the preferential adsorption of one ionic species from the solution phase (Babcock, 1963). Such a charge requires the presence of a layer of ions of opposite charge. The double layer consists of an excess of ions of opposite sign and a deficiency of ions of the same sign that are electrostatically repelled by the particle. Double layer theory assumes that the surface of the colloidal particles is represented by an infinite flat surface having continuous and uniform electrostatic charge density immersed in an electrolyte with a uniform dielectric constant (Babcock, 1963). All electrolyte ions are assumed to be point charges. The electrical potential, ion charge, and ion distributions can be calculated from the Poisson–Boltzmann equation:

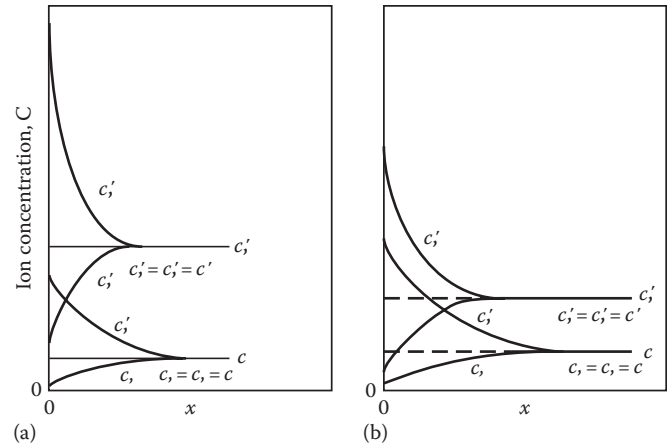
$$\frac{d^2\psi}{dx^2} = -\frac{1}{\varepsilon_0 D} \sum cFz_i \exp\left(-z_i F\psi(x)/RT\right) \qquad (15.26)$$


FIGURE 15.6 Distribution of ions in the electric double layer at two electrolyte concentrations ($c' > c$). (a) Constant potential surface. (b) Constant surface charge. (Adapted from van Olphen, H. 1977. An introduction to clay colloid chemistry, 2nd Ed. John Wiley & Sons, New York.)

where

   $\psi(x)$ is the inner potential at a distance x from the surface
   ε_0 is the permittivity of free space
   D is the dielectric constant of water
   c is the concentration
   R is the gas constant
   T is the temperature (K)
   F is the Faraday constant
   z_i is the valence of the charged species (Sposito, 1984)

Figures 15.6 and 15.7 present the ion distribution and the electric potential distribution, respectively, in the double layer at two electrolyte concentrations. The extent of the double layer is given by the distance $(1/\kappa)$ in units of meters:

$$\frac{1}{\kappa} = \sqrt{\frac{\varepsilon_0 RT}{2000 F^2 I}} \qquad (15.27)$$

where I is the ionic strength $\left(= 1/2 \sum c_i z_i^2\right)$. Important findings of diffuse double layer theory are (1) the excess cations near the negative surface neutralize more of the charge than the anion deficit, (2) the electric potential decreases as the electrolyte concentration increases, and (3) the double layer distance $(1/\kappa)$ decreases as the electrolyte concentration increases. Some important limitations of double layer theory are that it applies only to infinitely dilute suspensions and to low surface charge densities (Babcock, 1963).

15.2.2 Attractive Force

The attractive force acting on colloidal particles is called the van der Waals force and acts to bring particles closer together. The basis of the attractive force is that the fluctuating dipole of one atom polarizes another one and the two atoms attract
FIGURE 15.7 Electric potential distribution in the electric double layer at two electrolyte concentrations. (a) Constant potential surface. (b) Constant surface charge. (Adapted from van Olphen, H. 1977. An introduction to clay colloid chemistry, 2nd Ed. John Wiley & Sons, New York.)

FIGURE 15.8 van der Waals forces between two mica surfaces in aqueous electrolyte solutions. The measured Hamaker constant is $A = 2.2 \times 10^{-20}$ J. Retarded van der Waals forces are observed above 5 nm. (Reprinted from Israelachvili, J.N. 1992. Intermolecular and surface forces, 2nd Ed. Academic Press, San Diego, CA. With permission of Academic Press Ltd.)

each other. This attraction between atom pairs is additive, and, therefore, the energy of interaction between particles decreases much more slowly with distance than that between individual atoms (Quirk, 1994). The interaction energy per unit area between two opposing planar solids for the van der Waals force (Φ_{vdW}) is (Israelachvili, 1992)

$$\Phi_{vdW} = -\frac{A_H}{12\pi d^2} \qquad (15.28)$$

where
A_H is the Hamaker constant
d is the distance separating the solid surfaces

At distances >5 nm, the correlations between the induced dipole distributions weaken and the interaction energy per unit area corresponds to the retarded van der Waals force (Φ_{RvdW}):

$$\Phi_{RvdW} = -\frac{B_{rH}}{3d^3} \qquad (15.29)$$

where B_{rH} is the retarded Hamaker constant. Figure 15.8 shows values of the van der Waals force obtained experimentally between two mica surfaces. Attractive forces were observed between mica particles in the range of 0.6–2 nm in $CaCl_2$ solution both experimentally and theoretically with statistical mechanics and Monte Carlo simulations (Kjellander et al., 1990).

15.2.3 Repulsive Force

The electrostatic force results from the charge on the colloidal particles and acts to repel them. A force operates on charged surfaces as a result of their interacting double layers. This force is repulsive if the charges on the particles are the same. The repulsion described in terms of interaction energy per unit area (Φ_R) is given by the force times the distance through which it operates (Hiemenz, 1977; Sposito, 1984; Hiemenz and Rajagopalan, 1997):

$$\Phi_R = -\frac{64a^2}{z} cRT \exp(-z\kappa d) \qquad (15.30)$$

where
$a = \tanh(z\psi_0/4RT)$
z is the charge on the electrolyte ions
c is the concentration of the electrolyte ions
κ is the inverse double layer distance
d is half of the surface separation

This equation is valid only when the surface separation $2d \gg 1/\kappa$ and $a \approx 1$. The electrostatic force between two plates for different electrolyte concentrations is presented in Figure 15.9.

When surfaces are brought closer together, an additional repulsive force becomes important. This force is called the solvation force or, when water is the medium, the hydration force. Solvation forces are of short range and oscillatory and arise whenever liquid molecules are induced to order between surfaces. Between colloid surfaces, repulsive hydration forces arise when water molecules strongly bind to hydrogen bonding surface groups such as hydrated ions or hydroxyl groups (Israelachvili, 1992). The effective range of hydration forces in clays and silicas is 3–5 nm. The interaction of mica surfaces in dilute solution obeys double layer theory, but at higher electrolyte concentration, a hydration force
FIGURE 15.9 Repulsive force between two plates for different concentrations of a 1:1 electrolyte where κ is the inverse double layer distance. (Reprinted from Hiemenz, P.C. 1977. Principles of colloid and surface chemistry. Marcel Dekker Inc., New York. With permission of Marcel Dekker, Inc.)

develops due to the energy needed to dehydrate surface-bound cations. The strength of the hydration force, which increases with the hydration number of the cation: $Mg^{2+} > Ca^{2+} > Li^+ \approx Na^+ > K^+ > Cs^+$ (Pashley and Quirk, 1984; Israelachvili, 1992), is illustrated for two mica surfaces in Figure 15.10.
FIGURE 15.10 Forces between two mica surfaces in 7 mmol L^{-1} NaCl electrolyte. *F* is the total force scaled by the radius (*R*) of the curved surfaces. At distances > 1.5 nm, the forces are described by double layer theory. Hydration forces are observed at distances < 1.5 nm. (Reprinted with permission from Ducker, W.A., and R.M. Pashley. 1992. Forces between mica surfaces in the presence of rod-shaped divalent counterions. Langmuir 8:109–112. Copyright 1992 American Chemical Society.)

Clay swelling is the result of double layer repulsion between the surfaces of individual particles. Under confining conditions, a fluid pressure or swelling pressure is created that is a direct measure of the balance of forces between particles (van Olphen, 1977). The swelling pressure is obtained by measuring the confining force that must be applied to keep the clay layers at a given distance. The swelling pressure (Π) is

$$\Pi = P_{vdW} + P_R \tag{15.31}$$

where

P_{vdW} is the van der Waals force
P_R is the electrostatic force (Greathouse et al., 1994)

At short distances, hydration forces become significant in the swelling pressure. At greater distances, measured swelling pressures are of similar magnitude to calculated double layer repulsions (van Olphen, 1977).

Interparticle forces can be measured experimentally using the surface force apparatus (SFA), total internal reflectance microscopy, and the AFM (Israelachvili, 1992). The SFA can measure forces between surfaces at the 10^{-10} m level of resolution. This apparatus has been used to measure attractive van der Waals forces, repulsive double layer forces, and repulsive hydration forces in aqueous solutions (Israelachvili, 1992). Because of its smooth surface and ease of handling, mica has been the primary solid used in SFA studies. Total internal reflection microscopy has been used to study forces between a surface and an individual colloidal particle. AFM has been used to measure both short- and long-range forces (Ducker et al., 1991; Nishimura et al., 2002b; Zhao et al., 2008). Interactions between charged mica surfaces have been investigated using a combination of SFA and AFM experiments. Results from both methods agree with theoretical predictions (Kékicheff et al., 1993).

15.3 Colloidal Stability

15.3.1 Flocculation and Dispersion

The International Union of Pure and Applied Chemistry defines flocculation as "a process of contact and adhesion whereby the particles of a dispersion form larger-size clusters," other terms used interchangeably with flocculation are agglomeration and coagulation (IUPAC, 2009). The stability of colloidal suspensions is a balance between repulsive and attractive forces acting among the suspended particles. If net repulsive forces predominate, particles do not coagulate and remain dispersed. When the attractive forces are dominant, interacting particles coagulate and the resulting floccules settle more rapidly from the suspension than the smaller dispersed particles. Different theories in the literature attempt to describe colloid behavior (Sogami and Ise, 1984; Smalley, 1990; Ise and Smalley, 1994; McBride and Baveye, 2002). A classical continuum scale theory of the forces between particles is the DLVO theory named after Derjaguin, Landau, Verwey, and Overbeek, largely responsible

for its development (Hunter, 1987). Through the use of the SFA, it has been shown that the DLVO theory is an oversimplification of the forces acting at the mineral surface. For example, DLVO theory does not take into account short-range solvation forces (Israelachvili, 1992).

Continuum DLVO theory provides a simplified assumption of a phyllosilicate surface with permanent negative charge. Conceptually, the negative charge is developed from isomorphous substitution of lower valent cations for higher valent cations in either the tetrahedral or octahedral layers of the crystal. With regard to soils, a further complication exists in terms of mineral/organic interaction. Mounting evidence suggests that the primary reactive phases in soils are complex mineral assemblages where phyllosilicates are coated by natural organic matter and Fe-oxyhydroxide phases (Bertsch and Seaman, 1999). In this case, the theoretical models are too simplified to provide a good representation of natural colloids. Advanced computer molecular simulations must be used to begin to understand the complexities of mineral/fluid and mineral/mineral interaction, even for clean systems, for surface force behavior on the colloidal scale (Hsu, 1999). Consequently, DLVO theory, acknowledging its simplifications, will be used as a frame of reference for the discussion of flocculation dispersion.

Flocculation is a thermodynamically favorable process; however, the kinetics of coagulation determine the stability of colloidal suspensions. Generally, all colloidal suspensions will spontaneously flocculate given sufficient time, but potential energy barriers retard the rate of flocculation. These barriers are analogous to activation energies considered in chemical kinetics (Hiemenz and Rajagopalan, 1997). Particles in a primary minimum are adhesive and are not readily separated. In contrast, the dispersion/flocculation transition is the result of a secondary minimum, involves card-house type structures (Figure 15.11), and is readily reversible (Quirk, 1994).

There are many examples in the literature showing that DLVO theory can account for the observed kinetic behavior of dispersed colloidal systems (e.g., Napper and Hunter, 1974). However, this theory must be applied with caution since it treats ions exclusively as point charges ignoring their surface chemical

FIGURE 15.11 Representation of card-house structure. (Reprinted from Hunter, R.J. 1987. *Foundations of colloid science*, Vol. 1. Oxford University Press, New York by permission of Oxford University Press.)

properties and geometry, and should only be applied to dilute systems (Sogami and Ise, 1984).

The potential barrier preventing particles from coagulating is defined by the stability ratio (W), which is the fraction of the total number of collisions between particles that result in coagulation. The rate of coagulation in the absence of a potential barrier or rapid coagulation (R_f) is limited only by the rate of diffusion of the particles toward one another. When the particles have a potential barrier to overcome, the rate of coagulation (R_s) is slow and is related to R_f by

$$R_s = \frac{R_f}{W} \qquad (15.32)$$

Rapid coagulation occurs when no significant repulsive forces act between particles and van der Waals or long-range coulombic attractions predominate. The quantification of the coagulation rate under these conditions was examined by von Smoluchowski (1916, 1917) and is discussed by Overbeek (1952).

Slow coagulation occurs over distances of the order of 1–100 nm when the approaching particles experience a barrier as their double layers overlap. Diffusion over this distance results from many individual Brownian events, some of which bring the particles closer together and some of which take them further apart. Since the rates of rapid and slow coagulation are directly proportional to the number of particles diffusing in the direction of a central particle (J), it follows from Equation 15.32 that the stability ratio is given by

$$W = \frac{R_f}{R_s} = \frac{J_f}{J_s} = 2r \int_{2r}^{\infty} \exp\left(\frac{E_T}{K_B T}\right) \frac{dr}{d^2} \qquad (15.33)$$

where
  r is the particle radius
  $d \cong 2r$

Verwey and Overbeek (1948) showed that W was determined almost entirely by the value of the total potential energy (E_T) at the maximum (Figure 15.12). In Figure 15.12 E_R and E_A are the potential energies due to repulsive and attractive forces. A more complete analysis of the kinetics of colloid flocculation is presented in Hunter (1987).

Gravity removes suspended particles by sedimentation while inducing differential sedimentation coagulation, thereby decreasing Brownian coagulation rates. Ultimately, sedimentation limits the time of a flocculation series test. The test should be long enough to detect relative changes in suspended particle numbers, but not so long that all dispersed particles settle from a stable suspension (Hesterberg and Page, 1990a).

The reverse of flocculation is called dispersion. Ideally, the amount of energy required to separate two particles coagulated into a potential energy minimum is approximately equal to the difference between the interaction energy at the minimum and that at the adjacent maximum (van Olphen, 1977).
FIGURE 15.12 Total potential energy of interaction of two colloidal particles. $E_T = E_S + E_R + E_A$, where E_S is the potential energy of repulsion due to the solvent layers, E_R is the potential energy due to the repulsive forces, E_A is the potential energy due to the attractive forces, and κd is particle separation. (Reprinted from Hunter, R.J. 1987. Foundations of colloid science, Vol. 1. Oxford University Press, New York by permission of Oxford University Press.)

Under constant chemical conditions, separation of particles could presumably be induced by an input of kinetic energy (e.g., thermal or mechanical shear). Alternatively, changing the chemical conditions of the bulk solution surrounding coagulated particles could provide chemical and/or electrochemical energy to produce dispersion.

15.3.1.1 Modes of Particle Association

15.3.1.1.1 Edge–Edge, Edge–Face, Face–Face

Clay crystals have a net negative surface charge as a consequence of isomorphic substitutions of electropositive ions for ions with a lower valence. This negative charge generates an ionic reorganization in the solution medium that has been described above as the diffuse double layer. Clay particles also have edge surfaces with atomic structure different from the faces. At the edge of the platelet, the tetrahedral layer of Si and the octahedral layer of Al exhibit broken bonds, which, in turn, generate another electric double layer.

Double layer theory assumes that the surfaces of the clay minerals are of semi-infinite spatial extent and show no edge effects, a simplification that is not always satisfactory. Clay mineral particles have finite dimensions. Below the p.z.c., edge surfaces carry a positive charge due to specific adsorption of protons. Using the Poisson–Boltzmann equation, Secor and Radke (1985) calculated the effect of edge–face corners on the electrical potential distribution around an idealized, symmetrical montmorillonite disk. Spillover of the negative electrical potential from the particle faces into the edge region can result in a negative potential everywhere around the particle.

The electrical potential at the edge surface strongly depends on the electrolyte concentration and the ratio of the face to edge charge density. The extent of spillover also is a weak function of the particle shape (Secor and Radke, 1985). This study implies that attraction between positively charged edges and negatively charged faces of phyllosilicate mineral particles will depend on the extent of the edge protonation, electrolyte concentration, and shape of the particle. A phyllosilicate structure that is collapsed in the *c*-dimension, such as mica, should be able to acquire a larger edge surface charge density than a layer silicate like smectite where structural expansion increases the distance between edge surface aluminol groups (Hesterberg, 1988).

When there is a reduction in the thickness of the double layer, particles can associate among themselves in three different ways: face–face, face–edge, or edge–edge. Face–face association is also called parallel aggregation and does not produce floccules, while the other two associations do produce three-dimensional structures called card houses (see Figure 15.11).

In concentrated suspensions of clay, the edge–edge and edge–face associations form a continuum, with chains of particles in the card-house structures mentioned above. The rigidity of the gel depends on the number and strength of the bonds in the continuum structure. Some attempts to characterize the gel structure using freeze-drying techniques have been made (Norrish and Rausell-Colom, 1961). When the water is eliminated from the suspension, the volume of the system does not change and the final product is a dry clay structure with some strength that has been called aerogel (van Olphen, 1977).

15.3.1.1.2 Domains and Quasicrystals

Some colloidal systems may, under certain circumstances, show a reversible clustering among particles. The earliest reported example is the Fe-hydroxide sol described by Cotton and Mouton (1907). The term tactoid was first used by Freundlich (1932) and was more precisely defined by Overbeek (1952) as the association of particles at a certain distance affected by electrolyte concentration and pH. Quirk and Aylmore (1971) proposed the term quasicrystal to describe the regions of parallel alignment of individual aluminosilicate lamellae in montmorillonite and the term domain to describe the regions of parallel alignment of crystals for illite. This terminology is adopted in the present chapter.

The distribution model of adsorbed ions in mixed mono- and divalent systems for smectite quasicrystals was described by Shainberg and Otoh (1968) and Bar-on et al. (1970). According to this theory, called the ion demixing model, when Na is added to Ca saturated montmorillonite, most of the adsorbed Na will concentrate on the external surfaces of the quasicrystals until 10% of the adsorbed Ca has been replaced by Na. Initially, the size and shape of the particles are not altered by the addition of adsorbed Na. As further Na is added to the system, Na penetrates into the quasicrystals and brings about disintegration of the clay packets (Bar-on et al., 1970).

Lebron and Suarez (1992a) used electrophoretic mobility experiments to show that the demixing model can be applied to micaceous clays. The electrophoretic mobility of micaceous

TABLE 15.5 Critical Coagulation Concentrations of Phyllosilicates under Various Conditions

Mineral	CCC (mol$_c$ L^{-1})	Background Electrolyte	pH	Solids Concentration (g kg^{-1})
Kaolinite-4	2–40	NaNO$_3$	4–10	0.025
Kaolinite-9	8, 30	NaHCO$_3$, Na$_2$CO$_3$	8.3, 9.5	0.6–0.9
Kaolinite (Georgia)	5, 245, 75	NaCl, NaHCO$_3$, Na$_2$CO$_3$	7, 8.3, 9.5	0.6–0.9
Kaolinite (KGa-1)	<0.19–54.6	NaCl	5.8–9.1	0.67
Kaolinite-4	0.1–0.3	Ca(NO$_3$)$_2$	4–10	0.025
Kaolinite (KGa-1)	<0.19–0.85	CaCl$_2$	5.5–9.3	0.67
Montmorillonite-23	1–10	NaNO$_3$	3.8–10	0.25
Montmorillonite-23	20, 48, 68	NaCl, NaHCO$_3$, Na$_2$CO$_3$	7, 8.3, 9.5	0.6–0.9

domains increased when the sodium adsorption ratio (SAR) increased from 5 to approximately 10.

15.3.1.2 Critical Coagulation Concentration

The CCC, sometimes called the critical flocculation concentration (CFC), is the minimum concentration of indifferent electrolyte that induces rapid coagulation. The CCC is strongly dependent on counterion valence (Table 15.5). This observation is known as the Schulze–Hardy rule. An estimate of the CCC (mol L^{-1}) is given by (Hunter, 1987)

$$CCC = \frac{0.107\varepsilon^3 (k_B T)^5 Z^4}{N_A A_H^2 (ze)^6} \tag{15.34}$$

where
  $Z = \tanh(ze\psi_0/4k_B T)$
  N_A is Avogadro's number
  A_H is the Hamaker constant
  ε is the relative dielectric constant
  k_B is the Boltzmann constant
  e is the proton charge

The variation of CCC with counterion valence depends approximately on the inverse sixth power of z. At 25°C in water, using the experimental observation that coagulation usually occurs between low-potential surfaces, the result is

$$CCC \propto \frac{\psi_0^4}{z^2} \tag{15.35}$$

where now the CCC depends on the inverse of the square of the valence. However, the CCC calculated with Equation 15.35

agrees well with experimental results if $\psi_0 \propto 1/z$. When calculating the CCC in soils, one must consider that soils consist of mixtures of permanent and variable charge minerals. The net surface charge, and consequently, the electrical potential around the mixture of particles are dependent upon variables such as pH, specifically adsorbed ions, ionic strength, and mineralogy. A more detailed evaluation of the effect of these variables on the stability of colloids is presented below.

15.3.2 Factors Affecting Colloidal Stability

15.3.2.1 Solution Composition

The magnitude of the repulsion barrier is determined by the nature of the material adsorbed on the particle surface. In the case of a charged colloid, repulsion depends on the magnitude of the surface charge and on the extent of the electrical double layer, which, in turn, depends on the total electrolyte concentration. It is necessary here to distinguish between the concentration of the potential determining ions and that of other ions that have no direct interaction with the surface. If the surface potential of the particles is determined by the concentration of potential determining ions, the magnitude of this potential is not affected by the addition of an indifferent electrolyte. For this type of double layer, when salt concentration increases, the double layer thickness decreases, the surface charge of the particles increases, and the surface potential remains constant (Figure 15.7a).

If the surface charge of the particle is determined by isomorphic substitution, the surface charge does not change with increasing electrolyte concentration. The diffuse double layer compresses, but in this case, the surface potential decreases with increasing electrolyte concentration (Figure 15.7b) (van Olphen, 1977).

15.3.2.2 Exchange Complex Composition

As explained above, clay particles are surrounded by cations as a consequence of the net negative electrical charge on the surface. Cations bonded to the surface can be exchanged for other cations in solution. Consequently, the cations on the exchange complex are dependent on the solution composition.

There is an equilibrium between the cations on the exchange complex and the cations in the solution. Not all cations are adsorbed with the same affinity. Cations with larger hydrated radii are less strongly adsorbed than those with smaller hydrated radii. In solutions with equal initial concentration of different cations, the amounts of Ca and Mg adsorbed are several times greater than the amount of Na adsorbed. In general, polyvalent cations are adsorbed more strongly than monovalent cations and are not easily displaced by other cations. The order of adsorption strength is Al > Ca > Mg > H > K > Na (Duchaufour, 1970).

The flocculation/dispersion behavior of soil colloids depends on salt concentration, exchange complex cation, cation valence, and dominant clay mineralogy. In general, divalent cations are more effective in flocculating colloids than monovalent cations. For example, Quirk and Schofield (1955) found that the flocculating power of $CaCl_2$ is 50–100 times higher than that of NaCl. For monovalent cations, there is also a difference, with KCl showing greater flocculation power than NaCl (Pashley, 1981).

15.3.2.3 pH

The pH is an important determinant of the electrical potential of the clay surface. Changes in pH affect the edge charge on clays and the surface charge of variable charge minerals such as Fe and Al oxides. There is considerable variability depending on structural composition and degree of crystallinity, but Fe and Al oxides generally undergo a surface charge reversal around pH 7–9 (positively charged below that pH and negatively charged above). This is also the region in which kaolinite exhibits its edge charge reversal as evidenced by Cl^- adsorption studies (Schofield and Samson, 1954). Soil colloids consist of a mixture of minerals, each with a different p.z.c. At low pH, edge to face bonding, as well as bonding of positive Fe and Al oxides to negative clay surfaces, is expected to occur (van Olphen, 1977; Kretzschmar et al., 1993, 1997). This type of bonding should hinder dispersion and should thus result in flocculation. With increasing pH, as the p.z.c. is approached, edge to face clay bonding decreases and Fe and Al oxide bonding to clays is also expected to decrease (Suarez et al., 1984). In variable charge systems, flocculation is at a maximum at the p.z.c.

CCC increased at high SAR values with increasing pH for three soil clays whose clay mineralogy was dominantly kaolinite, montmorillonite, or illite (Goldberg and Forster, 1990). Hesterberg and Page (1990b) also found an increase in CCC for a Na- and a K-illite with increasing pH. Similar results were found for illite and three micaceous soil clays when SAR > 15 (Lebron and Suarez, 1992a, 1992b). The electrophoretic mobility of these materials increased when the SAR was greater than 20 and the pH was above the p.z.c. No pH effect was observed at SAR < 15 for either mobility or CCC.
FIGURE 15.13 Typical abundance of primary and secondary minerals in different size fractions of the soil. (Reprinted from McBride, M.B. 1994. Environmental chemistry of soils. Oxford University Press, New York by permission of Oxford University Press.)

15.3.2.4 Mineralogy

The colloidal fraction of a soil consists primarily of secondary minerals (Figure 15.13). Layer silicate minerals differ in chemical composition and charge characteristics leading to different physicochemical behavior (Table 15.5). The stoichiometry of each mineral varies due to isomorphic substitutions in the crystal lattice during the formation or evolution of the mineral structure.

The siloxane (Si–O–Si) surfaces of 2:1 layer silicates without structural charge are hydrophobic. Therefore, the surface oxygens coordinated to Si show little tendency to hydrogen bond with water molecules. Smectites, such as montmorillonite, form weak hydrogen bonds between structural charge located mainly in the octahedral sheet and water. Such bonds are the result of the delocalization of some structural charge into the surface oxygens (Farmer, 1978). Smectites, such as beidellite, with a high proportion of charge in the tetrahedral sheet, form stronger hydrogen bonds. The siloxane surfaces of vermiculite are the most hydrophilic of the 2:1 layer silicate clays because they possess a large tetrahedral charge partially distributed onto surface oxygens (Farmer, 1978). Tetrahedral charge is much more localized on fewer surface oxygens than octahedral charge, explaining the stronger hydrogen bonding of adsorbed water on vermiculite (McBride, 1989). An extensive study of the structural characteristics of soil minerals can be found in Dixon and Weed (1989).

An example of how these mineral differences affect the flocculation/dispersion behavior of soil colloids is shown in Table 15.5. An overview of the data reveals that reported CCC values of kaolinite, montmorillonite, vermiculite, and illite are quite variable within and between these mineral groups.

Many of the differences in Table 15.5 are due to differences in methodology in the determination of CCC and/or differences in the stoichiometry of the silicate minerals. However, these factors do not account for all of the variability. Lebron and Suarez

(1992a) found substantial differences in CCC within samples from the same soil type. Differences in content of organic matter and other minerals can drastically change the behavior of soil colloids. Consequently, general guidelines for reclamation of agricultural land or the use of amendments to maintain colloids in a flocculated state must be implemented with caution because soils usually require higher electrolyte concentrations than the corresponding pure clay minerals to maintain a flocculated condition.

15.3.2.5 Organic Matter

Organic matter constitutes a small portion of the soil mass (0.5%–10%) but is intimately associated with inorganic particles and plays an important role in the improvement of soil structure (Nelson and Oades, 1998). Aeration, water-holding capacity, and permeability increase with increasing soil SOM content. However, adsorbed organic matter can promote dispersion of soil particles. Organic coatings, under certain conditions, maintain a dispersed state for soil colloids in suspension through a combination of electrostatic and steric mechanisms (Stevenson, 1982). Table 15.6 shows the spatial extensions for nonionic polymer molecules of different molecular weights. Like electrical double layers, macromolecules of at least a few thousand molecular weight also extend in space over distances comparable to, or greater than, the van der Waals attraction. In general, it has been shown that organic matter coatings modify the surface properties of minerals, increasing their CEC, generating hydrophobic and hydrophilic surfaces (Hunter, 1987), and significantly altering the point of zero net charge (p.z.n.c., pH at which the CEC and AEC are equal) (Heil and Sposito, 1993; Kaplan et al., 1997; Kretzschmar et al., 1997; Bertsch and Seaman, 1999).

Goldberg and Forster (1990) and Kretzschmar et al. (1993) found that the removal of SOM enhanced soil flocculation (decreased the CCC). Similarly, addition of small amounts of organic material substantially increased dispersion of Na-saturated soil or clay in the order: humic acid > soil polysaccharide ≥ anionic polysaccharide (Gu and Doner, 1993; Kretzschmar et al., 1997). Using smectite, kaolinite, and three soils whose clay fractions were dominated by one of these minerals, Frenkel et al. (1992) showed that the CCC values of Na-soils were much higher, and much more affected by organic matter than those of Ca-soils.

TABLE 15.6 Spatial Extensions of Electrical Double Layers and Polymers of Different Molecular Weight

1:1 Electrolyte Concentration (mol L^{-1})	Double-Layer Thickness, $1/\kappa$ (nm)	Polymer Molecular Weight	Spatial Extension (nm)
10^{-5}	100	1,000,000	60
10^{-4}	30	100,000	20
10^{-3}	10	10,000	6
10^{-2}	3	1000	2
10^{-1}	1

FIGURE 15.14 Effect of the humic acid concentration on the CCC of a Na-clay and a Ca-clay. (After Tarchitzky, J., Y. Chen, and A. Banin. 1993. Humic substances and pH effects on sodium and calcium-montmorillonite flocculation and dispersion. Soil Sci. Soc. Am. J. 57:367–372.)

Tarchitzky et al. (1993) showed similar comparisons between Na- and Ca-montmorillonite suspensions with varying additions of humic and fulvic acids (Figure 15.14). The effect of organic matter on stability of soil colloids is a function of its size. Large organic materials such as polysaccharides and hyphae act to bind colloid particles together. Small organic molecules such as fulvic acid and organic acids increase dispersion of soil colloids through their effect on particle charge. A more detailed review of organic matter chemistry and its effect on soils is provided in Stevenson (1982) and Nelson and Oades (1998).

15.3.3 Measurement of Colloidal Stability

15.3.3.1 Flocculation Series Test

CCC are commonly determined using the flocculation series test. The experiment can be performed by taking a series of test tubes containing the same concentration of the colloid and adding varying amounts of the coagulating electrolyte. The tubes are then shaken and allowed to stand for a given time. If the electrolyte range has been properly chosen, the CCC is defined as the concentration above which the settling material leaves behind a perfectly clear supernatant solution. Below the CCC, the supernatant retains some of the uncoagulated colloid. The concentration of colloidal particles at which the flocculation test must be performed should not exceed 10 g L^{-1}, thus avoiding interferences from different particle interactions such as gel formation.

15.3.3.2 Dispersion Indices

There are several methods (qualitative, semiquantitative, and quantitative) to determine the dispersion or flocculation status of soil colloids. Qualitative analyses of the dispersion state are those based on direct observation of small particles when the soil is immersed in water. This observation can be made with the optical microscope or with the naked eye, as is the case for

the test of Emerson (1967). Methods based on turbidity of a suspension of dispersed soil can be considered semiquantitative when comparative measurements are made. Normally, a standard curve is constructed using known amounts of dispersed clay. The soil under evaluation is assigned a dispersion value by comparison with the standard. The most commonly used quantitative method to determine soil flocculation state is the dispersion index. This index is the ratio of the amount of soil colloids in water to the amount of soil colloids in solution when the soil has been treated with a dispersant. This procedure is recommended by the Soil Conservation Service (Sherard et al., 1977). Different variations regarding particle size, dispersing agent, and manipulation of samples are found in the methods proposed by El-Swaify et al. (1970) and Dong et al. (1983), among others.

15.3.3.3 Bingham Yield Stress

Rheology is the study of the flow and deformation of colloidal systems under the influence of mechanical forces (van Olphen, 1977). A Newtonian liquid when confined between two parallel plates moves at a constant shear rate ($\dot{\gamma}$) proportional to the applied shear stress (τ):

$$\tau = \eta\dot{\gamma} \qquad (15.36)$$

Non-Newtonian fluids obey different relations between shear stress and shear rate. Plastic flow is flow that occurs only above a certain finite stress (τ_0) called the yield stress. Ideal plastic flow exhibits a linear relationship between shear rate and shear stress over all rates of shear. Many colloidal dispersions exhibit Bingham flow, which is characterized by the equation

$$\tau = \tau_B - \eta_\Delta\dot{\gamma} \qquad (15.37)$$

where
  τ_B is the Bingham yield stress found by extrapolating Equation 15.37 to zero shear rate
  η_Δ is the differential or plastic viscosity

The differential viscosity is the derivative of shear stress with respect to shear rate at a given shear rate (van Olphen, 1977). Shear rate versus shear stress relationships for Newtonian flow, ideal plastic flow, and Bingham flow are presented in Figure 15.15.

  Bingham yield stress is a measure of the degree of coagulation of a colloidal suspension and the mode of particle interaction. Bingham yield stress is a function of both the number of particle–particle linkages in the coagulated structure and the energy required to break these linkages (Rand and Melton, 1977). A stable clay dispersion exhibits ideal plastic flow, while flocculated suspensions exhibit Bingham flow as can be seen in Figure 15.16 for kaolinite. Differential viscosity can also be used to assess the extent of particle flocculation, but it is a much less sensitive parameter than Bingham yield stress (Heath and Tadros, 1983).

  Rheological studies have been carried out on kaolinite (Flegman et al., 1969; Rand and Melton, 1977; Yong et al., 1979; Diz and Rand, 1989; Ma and Pierre, 1999), illite (Yong et al., 1979;
FIGURE 15.15 Shear rate versus shear stress relationships. Curve a represents Newtonian flow, curve b represents ideal plastic flow, and curve c represents Bingham flow. (Adapted from van Olphen, H. 1977. An introduction to clay colloid chemistry, 2nd Ed. John Wiley & Sons, New York.)
FIGURE 15.16 Shear rate versus shear stress for Na-kaolinite. The open symbols represent dispersed systems and ideal plastic flow. The closed symbols represent coagulated systems and Bingham flow. (Adapted from Yong, R.N., A.J. Sadh, H.P. Ludwig, and M.A. Jorgensen. 1979. Interparticle action and rheology of dispersive clays. J. Geotech. Eng. Div. 105:1193–1209.)

Ohtsubo et al., 1991; Hesterberg and Page, 1993), montmorillonite (Rand et al., 1980; Heath and Tadros, 1983; Keren, 1988, 1989a; Tombácz et al., 1989; Miano and Rabaioli, 1994; Benna et al., 1999; Duran et al., 2000), laponite (Laxton and Berg, 2006), clay mixtures (Yong et al., 1979; Keren, 1989b, 1991), soil clays (Zhao et al., 1991), and soils (Ghezzehei and Or, 2001; Markgraf et al., 2006). A series of curves of Bingham yield stress as a function of pH obtained at successively increasing electrolyte concentration should coincide at one point. This point is characteristic of the pH value of the edge p.z.c. of the mineral (Rand and Melton, 1977). Edge p.z.c. values have been determined in this manner for various kaolinites and range in value from pH 5.6 to 8.8 (Diz and Rand, 1989). Kaolinite particles occur in edge–face associations below the edge p.z.c. and in edge–edge associations around the edge p.z.c. (Rand and Melton, 1977).

Montmorillonite exhibits no edge–face associations over the pH range 4–11; coagulation produced by electrolyte additions is initially the result of edge–edge interactions with face–face interactions occurring at high-electrolyte concentrations (Rand et al., 1980). No edge p.z.c. could be determined on montmorillonite using this method. This is likely because the edge area is small and attraction between edges and faces is small compared to repulsion between faces (Rand et al., 1980). From yield stress and electrophoretic mobility measurements determined without electrolyte addition, Benna et al. (1999) suggested that the p.z.c. of three bentonites occurred in the pH range of 7.5–8.5.

In distilled water, Ca-montmorillonite exhibited Newtonian flow. With increasing exchangeable sodium percentage (ESP), differential viscosity, deviation from Newtonian flow, and Bingham yield stress of montmorillonite all increased (Keren, 1988). These increases are likely due to the increased number of particles in solution as tactoids break down. Differential viscosity and Bingham yield stress decreased with increasing electrostatic charge density of smectites (Keren, 1989a). This result is attributed to the reduced swelling of higher charge density smectites. Kaolinite exhibited Newtonian flow at all ESPs. The introduction of even 5% montmorillonite into the kaolinite systems resulted in deviations from Newtonian flow and increased differential viscosity (Keren, 1989b). Bingham yield stress and deviations from Newtonian flow of kaolinite–montmorillonite mixtures also increased with ESP (Keren, 1991). Bingham yield stress of kaolinite, Ca-montmorillonite, Na-montmorillonite, and two soils increased exponentially with decreasing water content (Ghezzehei and Or, 2001).

15.4 Colloid Transport

As previously discussed, colloidal materials found in soils include phyllosilicate clays, Al, Fe, and other metal oxides, carbonate minerals, microorganisms, and other biological debris, much of which falls into the "nanoparticle" size range (see Section 15.1.2). The fundamental processes involved in colloid migration in the soil environment include mobilization, transport, and deposition, representing primarily a balance between the two opposing processes of colloid mobilization and deposition. The study of colloid transport in the subsurface environment has received considerable attention in recent years because of concern that mobile colloids may enhance the mobility of strongly sorbing contaminants (i.e., facilitated transport) and alter the hydraulic properties of soil and aquifer materials. In addition, the migration of biocolloids such as bacteria and viruses has important implications to in situ bioremediation, the protection of drinking water supplies, and the spread of disease (Khilar and Fogler, 1984; McDowell-Boyer et al., 1986; Kia et al., 1987; Ryan and Elimelech, 1996; Kretzschmar et al., 1999; de Jonge et al., 2004b; McCarthy and McKay, 2004; Tufenkji, 2007). However, our ability to predict colloid movement and deposition is often confounded by the complexities of surface interactions in such heterogeneous natural systems. Understanding colloid transport requires consideration not only of the chemical and biological processes and reactions but also of the physical principles of filtration and deposition in porous media.

Several mechanisms have been identified by which colloidal materials can be mobilized in the soil environment (Figure 15.17) including clay dispersion resulting from changes in pore-water chemistry that increase electrostatic repulsion between the colloid and collector surfaces, water film expansion and air–water interface scouring during episodic wetting events (imbibition), raindrop impact at the soil surface, and increased shear forces associated with transient hydrodynamic events (i.e., precipitation, groundwater pumping, subsurface recharge injection). Mobile colloids can also be formed in situ through precipitation reactions resulting from changes in pore-water chemistry. Clearly, colloid mobilization is associated with a physical and/or chemical perturbation sufficient to overcome the energy barrier limiting particle detachment (McCarthy and Degueldre, 1993; Ryan and Elimelech, 1996; DeNovio et al., 2004).

Compared to saturated aquifer systems, chemical and physical perturbations are common within the soil environment, with the presence of air providing an additional system interface for colloid partitioning (Wan and Wilson, 1994; Sirivithayapakorn and Keller, 2003). The presence of a dynamic air–water interface and fluctuating chemical and hydrological conditions complicate our understanding of colloid transport processes in the soil and vadose environments (Bradford and Torkzaban, 2008). Preferential flow paths can increase the mobility of colloidal material in close proximity to the pathway, while limiting the reactivity of colloidal sorbents isolated from the flow path (DeNovio et al., 2004; McCarthy and McKay, 2004).

The energy barrier limiting colloid detachment is the difference between the interaction minimum and the maximum energy potential described in Figure 15.12. In terms of chemical perturbations, soil colloid mobilization can result from changes in pore-water pH, ionic strength, and/or Na^+/Ca^{2+} ratios (McDowell-Boyer, 1992; Ryan and Gschwend, 1994; Gamerdinger and Kaplan, 2001; Bunn et al., 2002; Khaleel et al., 2002; McCarthy et al., 2002; Grolimund and Borkovec, 2006), alteration of surface charge resulting from a chemical dispersing agent or dissolved organic matter (Ryan and Gschwend, 1994; Seaman and Bertsch, 2000; Johnson et al., 2001), or dissolution of carbonate or Fe cementing agents resulting in the release and transport of silicate clays (Gschwend et al., 1990; Ryan and Gschwend, 1990; Ronen et al., 1992; Swartz and Gschwend, 1998). Furthermore, potentially mobile colloids may precipitate in situ due to altered chemical gradients (Gschwend and Reynolds, 1987; Mashal et al., 2004). In many instances, more than one of the mechanisms may be operative in order to trigger significant colloid mobilization, such as a change in pore-water chemistry that reduces particle attraction combined with an increase in pore-water velocity and shear forces.

Under ideal laminar flow conditions, the hydrodynamic shear force acting on a spherical particle attached to a flat surface can be expressed as follows:

(a)

(b)
FIGURE 15.17 Colloid mobilization (a) mechanisms include dispersion due to chemical perturbation, expansion of water film during imbibition, air–water interface scouring and shear mobilization. Colloid deposition (b) mechanisms include attachment associated with physicochemical filtration, attachment to the air–water interface, physical pore straining, and water film straining. (Adapted from DeNovio, N.M., J.E. Saiers, and J.N. Ryan. 2004. Colloid movement in unsaturated porous media: Recent advances and future directions. Vadose Zone J. 3:338–351.)

$$F_{shear} = (1.7)6\pi\mu rV \qquad (15.38)$$

where

   V is the flow velocity at the center of the particle
   μ is the fluid viscosity
   r is the particle radius (Sharma et al., 1992; Ryan and Elimelech, 1996; Ryan et al., 1998; DeNovio et al., 2004)

Adhesive forces that oppose shear stress are subject to changes in solution chemistry. The critical velocity for particle release decreases with increasing particle size, even though the required hydrodynamic force increases for non-Brownian particles, that is, >1 μm in diameter (Sharma et al., 1992). As one might expect, the amount of particles mobilized should generally increase with increasing flow velocity, but greater flow velocities are required to mobilize smaller particles that extend to a lesser degree into

the advective stream. However, many assumptions inherent in applying such a physical approach to soil and aquifer systems are likely in question. In more realistic systems, interrelated factors such as contact area, adhesion strength, and surface charge heterogeneity are important in countering shear forces (Sharma et al., 1992).

In addition to the chemical factors affecting colloid stability, transport of colloids is related to soil physical factors such as pore size distribution, geometry, and continuity (Torkzaban et al., 2008; Bradford et al., 2009). Coarse-textured soils have a larger distribution of pore sizes (with larger pores) than fine-textured soils, suggesting greater potential for colloid movement. This is not generalizable since some fine-textured materials experience cracking and formation of continuous structural macropores that provide a preferential pathway for colloid transport.

15.4.1 Colloid Transport Modeling

Physical and chemical processes affect the transport of soil colloids. Colloid transport can be represented by the physical processes of molecular diffusion (Brownian movement), advective flow, and gravitational forces. Molecular diffusion, the random motion of particles caused by thermal effects, is related to temperature and viscosity. Deposition is the process whereby moving particles are attached to stationary surfaces based on the balance of attractive and repulsive forces, that is, attractive van der Waals forces and the combined influence of attractive and repulsive electrostatic forces, as described by DLVO theory of colloid stability (see Sections 15.2.2, 15.2.3, and 15.3.1).

The attachment process involves two steps: transport to the collector surface and attachment that binds the two surfaces together. The transport step reflects a combination of diffusion, convection, and gravity, with electrostatic and van der Waals forces controlling colloid binding. Models used in describing colloid transport are typically extensions of the advection dispersion equation (ADE) for describing solute movement in a homogeneous saturated porous medium:

$$\frac{\partial C}{\partial t} + \frac{\rho_b}{\theta}\frac{\partial S}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - \nu\frac{\partial C}{\partial x} \qquad (15.39)$$

where
  C is the aqueous phase concentration for the solute or suspended colloidal material of interest
  x is distance
  t is time
  D is the hydrodynamic dispersion coefficient
  ν is the pore-water velocity
  S is the sorbed concentration of colloids or solutes
  ρ_b is the matrix bulk density
  θ is the volumetric water content (Grolimund and Borkovec, 2001; Bradford et al., 2003; Tufenkji, 2007)

Hydrodynamic dispersion and dispersivity appear to decrease with increasing particle size (Sinton et al., 2000; Auset and Keller, 2004). As the colloidal material moves through porous medium, it may be removed from solution by various physicochemical filtration processes, with various expressions, such as the equilibrium partitioning (K_{eq}), used to describe reversible colloid attachment processes in a manner analogous to the equilibrium partitioning of solutes. Using a numerical solution to the ADE, equilibrium partitioning can be modified to reflect any one of a variety of phenomenological equilibrium partitioning expressions, that is, Freundlich, Langmuir, etc.

In contrast to equilibrium partitioning, colloid attachment is more often viewed as a kinetically controlled process with terms accounting for both attachment (k_{att}) and detachment (k_{det}) rates:

$$\frac{\rho_b}{\theta}\frac{\partial S}{\partial t} = k_{att}C - \frac{\rho_b}{\theta}k_{det}S \qquad (15.40)$$

yielding an expression that is mathematically equivalent to the reversible first-order kinetic equation for partitioning solutes. Ripening and blocking are terms that are used to describe an increase or decrease in colloid attachment efficiency (i.e., k_{att} and k_{det}) with time or distance.

Figure 15.18 illustrates colloid breakthrough behavior for irreversible (Figure 15.18a) and reversible (Figure 15.18b) attachment kinetics. Colloid attachment is commonly assumed to be irreversible (i.e., $k_{det} = 0$) as described by clean-bed colloid filtration theory (CFT) (O'Melia and Tiller, 1993; Bradford et al., 2003; Simunek et al., 2006; Tufenkji, 2007). For irreversible attachment (i.e., CFT), the kinetic rate coefficient determines the plateau level of colloid breakthrough, while more complex breakthrough behavior is observed when both attachment and detachment occur at differing rates. When $k_{att} = k_{det}$, colloid behavior becomes analogous to that of a conservative tracer, that is, $R = 1$. Colloid retention profiles for irreversible attachment (Figure 15.18c) remain unchanged after the inlet colloid source is removed and an exponential decrease in retained colloids is observed with transport distance. Again, a more complex colloid retention profile is observed for reversible attachment that depends on both the forward and reverse rate coefficients and the treatment duration (Figure 15.18d).

The irreversible colloid attachment/depositional rate constant for a clean-bed filter is

$$k_{att} = \frac{3(1-\theta)\nu}{2d_c}\eta_0\alpha \qquad (15.41)$$

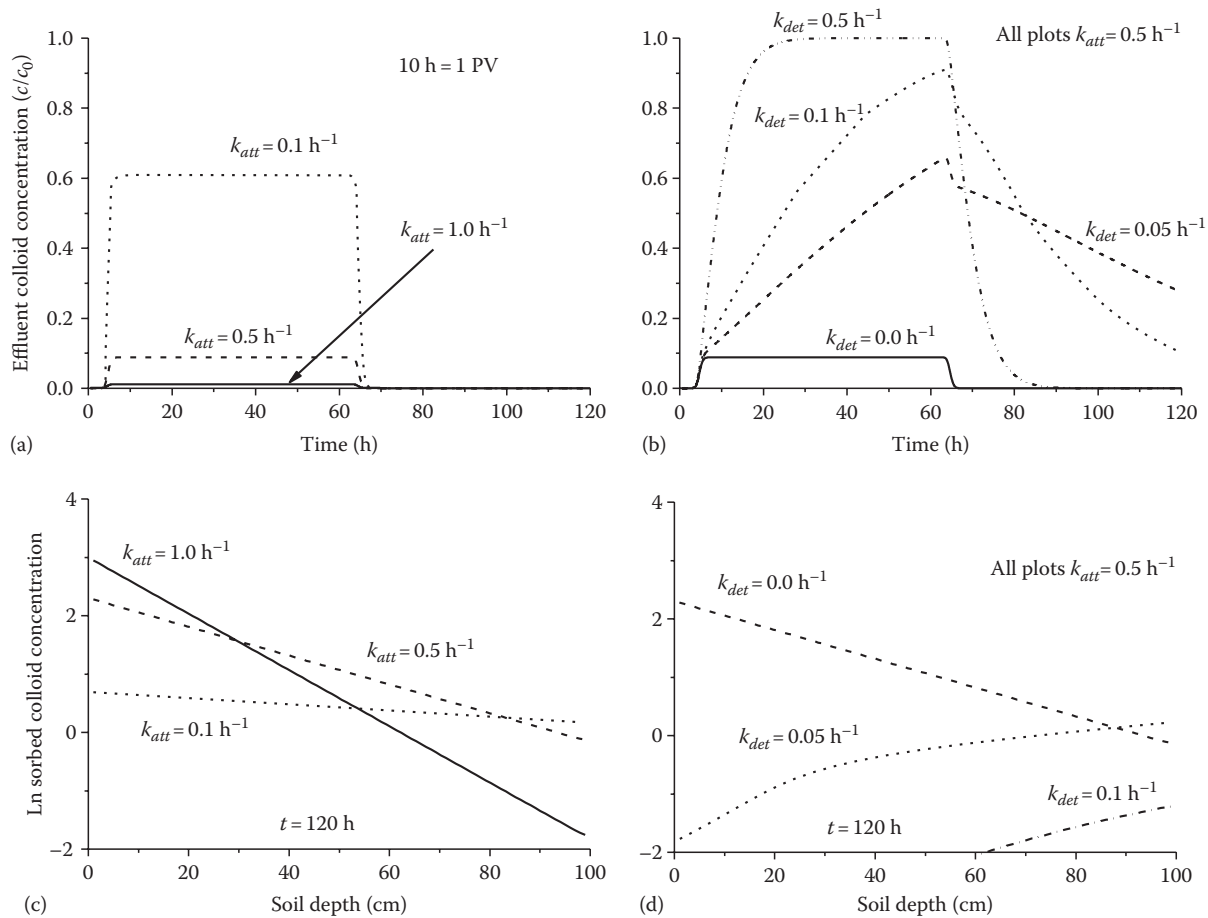
where
  d_c is the average grain size of the matrix
  η_0 is the collector contact efficiency for the three transport mechanisms (diffusion, gravity, convection)
  α is the attachment efficiency (Yao et al., 1971; Bradford et al., 2003; Li et al., 2004)


FIGURE 15.18 Simulated colloid breakthrough for a 1 m column with a saturated flow velocity of 2.4 m day^{-1} ($\theta = 0.5$, DL = 0.01 m) exposed to a 60 h colloid pulse with kinetically controlled attachment (a = clean-bed filtration theory), and kinetically controlled attachment and detachment (b). Retained colloid profile for irreversible (c), and reversible attachment (d) after 60 h colloid pulse followed by 60 h of colloid-free inlet solution.

The collector efficiency reflects the colloid collisions with the stationary matrix resulting from diffusion, advective flow, and gravitational forces, and can be calculated (Tufenkji and Elimelech, 2004a). The attachment efficiency term (α) is generally determined experimentally by fitting colloid breakthrough results to the CFT model based on k_{att} and the calculated η (O'Melia and Tiller, 1993; Elimelech et al., 2000; Bradford et al., 2004; Tufenkji and Elimelech, 2004a; Tufenkji, 2007). Additional mechanisms of material loss, such as cell motility, growth, and inactivation, must also be considered when evaluating the transport of microbes. Furthermore, research in the last decade has demonstrated the importance of surface biomolecules, which can vary in response to the local environment, and among microbial strains and species in controlling their adhesion properties (Bolster et al., 2000; Walker et al., 2004; Tufenkji, 2007).

Studies using model colloidal systems indicate that CFT is generally applicable under conditions favoring particle attachment, that is, no significant electrostatic repulsion. However, the CFT approach fails in describing experimental data under apparently unfavorable conditions when significant electrostatic repulsion exists between the mobile colloid and matrix

grain surface. For particles with the same charge, a deep primary attractive force exists at very short separation distances, known as the primary minimum (Figure 15.12). However, electrostatic repulsion supposedly limits particle approach in a manner similar to chemical activation energies. Such discrepancies in deposition studies, and in batch aggregation experiments, have been attributed to porous media heterogeneity that can be difficult to quantify experimentally (i.e., grain size, morphology, and surface charge) and a secondary energy minimum that favors colloid sorption without the necessity to overcome the full electrostatic repulsion required to enter the primary minimum (Figure 15.12), resulting in an apparent change in the attachment rate coefficient (k_{att}) with transport distance (Roy and Dzombak, 1996; Elimelech et al., 2000; Chen et al., 2001; Bradford et al., 2002, 2003; Tufenkji et al., 2003; Hahn and O'Melia, 2004; Li et al., 2004; Redman et al., 2004; Tufenkji and Elimelech, 2005; Tufenkji, 2007). The secondary minimum reflects the exponential decay in electrostatic forces with separation distance, in contrast to van der Waals forces that decrease more slowly with distance. The inability to remobilize particles trapped within the "secondary" minimum by altering solution chemistry, that is, reducing ionic strength, further demonstrates the hydrodynamic

and physicochemical complexity of colloid retention mechanisms (Bradford and Torkzaban, 2008; Torkzaban et al., 2008; Bradford et al., 2009).

Verifying the spatial distribution of retained colloids based on the attachment parameter (α_{BTC}) derived from effluent breakthrough data is a good method for testing the validity of the CFT model. In many instances, the slope of the relationship is greater than CFT predictions, indicating higher initial colloid retention that decreases with increasing transport distance (Li et al., 2004; Tufenkji, 2007). Such discrepancies have been addressed through the use of multiple deposition rate constants, that is, a fast and a slow rate, or a defined statistical distribution of randomly assigned particle deposition rates that reflect the inherent variability in colloidal surface potentials (Li et al., 2004; Tufenkji and Elimelech, 2004b; Tufenkji, 2007). It is interesting to note that the statistical distribution in observed deposition rate coefficients appears to narrow as colloid deposition becomes more favorable, for example, reduced flow velocities and increased ionic strengths (Li et al., 2004).

Attachment kinetics are highly sensitive to colloid–collector interaction potentials. Moderate changes with respect to colloid surface potentials can result in relatively large changes in collision efficiency and attachment rate (Elimelech and O'Melia, 1990; Ryan and Elimelech, 1996; Elimelech et al., 2000; Li et al., 2004). Deviation from the breakthrough plateau with time is indicative of a change in the colloid deposition efficiency during the course of injection, that is, filter ripening or blocking. In addition, surface modifiers such as Fe oxides and soil organics, often present in relatively minor amounts, can alter the expression of electrostatic repulsion on soil mineral surfaces (Goldberg and Forster, 1990; Kretzschmar et al., 1993; Kaplan et al., 1993, 1997; Bertsch and Seaman, 1999; Franchi and O'Melia, 2003; Seaman et al., 1995, 2003).

Recent studies indicate that pore structure and particle straining may also be more significant than previously recognized for intermediate colloid and matrix grain sizes. Colloid straining, trapping colloids in pore regions that are too small to permit passage, is generally considered to be an irreversible process. Within a transport model, straining can be addressed by including an additional first-order expression to the deposition equation given above. In the absence of colloid detachment, the kinetic deposition model accounting for colloid straining becomes

$$\frac{\rho_b}{\theta}\frac{\partial S}{\partial t} = k_{att}C - k_{str}\psi_{str}C \tag{15.42}$$

where
> k_{str} is the straining rate constant
> ψ_{str} is the depth-dependent colloid straining function (Bradford et al., 2002, 2003, 2004)

In contrast to straining, traditionally considered a physical phenomenon insensitive to solution chemistry, recent hydrodynamic modeling efforts have verified particle capture within hydrodynamically disconnected regions of the porous matrix near two collector particle surfaces where the magnitude of fluid velocity is quite small compared to the bulk solution, analogous to the "immobile" regions evident in solute transport behavior. Within the immobile regions, greater colloid/colloid and colloid/collector surface interactions lead to enhanced colloid immobilization in a manner that depends on both solution chemistry and pore geometry. Furthermore, particles weakly retained in the secondary minimum can be subsequently funneled to the immobile capture regions by hydrodynamic forces that are insufficient to induce full colloid detachment (Bradford and Torkzaban, 2008; Torkzaban et al., 2008; Bradford et al., 2009).

15.4.2 Colloid-Mediated Contaminant Transport

Numerous studies have established that organic and inorganic chemicals, which are highly sorbed onto soil nonetheless, are often transported in the subsurface to a greater degree than expected. Such anomalies have been attributed to kinetic effects associated with nonequilibrium sorption and bypass flow, as well as contaminant transport associated with a mobile colloidal fraction that enhances apparent migration beyond the levels controlled by thermodynamically based solubilities or partitioning reactions. Furthermore, colloidal materials may move at rates that are similar or faster than those of nonreactive solute tracers because of physical size or electrostatic exclusion from a fraction of the saturated pore space (Simunek et al., 2006). In general, colloid-facilitated transport is only significant when the contaminant is strongly sorbed to the mobile colloidal phase, approaching irreversible partitioning. Otherwise, the sorbed contaminant will desorb in response to the decrease in the aqueous phase contaminant concentration when the colloidal phase travels faster than the aqueous phase (Grolimund and Borkovec, 2005).

Models that include colloid-facilitated transport generally differ in the manner in which they account for the various colloid release and attachment processes described in Section 15.4.1 (i.e., reversible vs. irreversible attachment, kinetic vs. equilibrium) (Mills et al., 1991; Dunnivant et al., 1992; Corapcioglu and Jiang, 1993; Grolimund and Borkovec, 2005) with additional equilibrium or kinetic expressions used to account for contaminant–colloid interactions. Only recently have models been developed that address partially saturated conditions, colloid straining, and size exclusion (Simunek et al., 2006). The development of such a contaminant transport model, while requiring numerous simplifying assumptions (van de Weerd and Leijnse, 1997; Simunek et al., 2006), still results in a significant list of parameters required to account for both contaminant sorption and colloid attachment. For example, transport and mass balance expressions must account for the aqueous phase contaminant, contaminant sorbed to the immobile matrix, contaminant sorbed to the mobile colloids, and contaminant sorbed to colloids immobilized by various mechanisms, that is, stationary phase attachment, air–water interphase attachment, and straining. Additional expressions are required to account for colloid mass balance as well, illustrating the potential level of model

complexity. Simunek et al. (2006) recommend the use of sensitivity analysis to discern the relative importance of such variables in accurately describing contaminant fate and transport.

Although subject to numerous sampling artifacts, significant concentrations of mobile colloids have been observed in soil and groundwater systems (Ronen et al., 1992; McCarthy and Degueldre, 1993; DeNovio et al., 2004). However, contaminant transport models generally fail to account for the impact of mobile colloids in facilitating the transport of strongly sorbing contaminants. For example, colloid-facilitated transport has been implicated in the migration of organic contaminants (e.g., atrazine, prochloraz, and dichlorodiphenyltrichloroethane [DDT]) (Vinten et al., 1983; Seta and Karathanasis, 1996; Seta and Karathanasis, 1997; de Jonge et al., 1998; Roy and Dzombak, 1998), metals (e.g., Pb, Ni, Cu, and Zn) (Kaplan et al., 1994b, 1995; Grolimund et al., 1996; Roy and Dzombak, 1997; Karathanasis, 1999; Grolimund and Borkovec, 2005; Karathanasis et al., 2005), radionuclides (e.g., ^{137}Cs) (Von Gunten et al., 1988; Kaplan et al., 1994a; Kersting et al., 1999; Flury et al., 2002), and sparingly soluble nutrients, such as phosphate (de Jonge et al., 2004b). Some of the general issues concerning contaminant migration via colloid-facilitated transport are discussed by McDowell-Boyer et al. (1986), McCarthy and Zachara (1989), Ryan and Elimelech (1996), and Kretzschmar et al. (1999).

15.4.3 Effect of Colloid Transport on Hydraulic Conductivity and Soil Formation

Some degree of colloid movement is generally considered a major factor in soil profile development. However, dispersion and transport of soil colloids have been linked to soil crust formation, reduced infiltration and hydraulic conductivity, and erosion (Shainberg et al., 1981; Miller and Baharuddin, 1986; Miller and Radcliffe, 1992). Reductions in hydraulic conductivity caused by colloid transport can be divided into two groups: formation of crusts and migration and deposition within the medium. Crust formation results when the colloids are not able to enter the soil media and form a compact layer above the soil. Alternatively, the particles may enter the medium, flow with the water in a suspension, and be deposited within the medium. This process may result from either mechanical filtration of large colloids or physicochemical processes of attraction/repulsion of small colloids as discussed above (see Section 15.4.1).

Research in soil science related to the effects of colloid transport on hydraulic conductivity has focused primarily on description of the chemical process affecting clay movement, rather than on mathematical expressions for prediction of flow rates. Conditions of low ionic strength, high exchangeable Na, and elevated pH were related to both dispersion of clays (Suarez et al., 1984; Goldberg and Forster, 1990; Miller et al., 1990) and subsequent migration and reduction in soil hydraulic conductivity (Suarez et al., 1984). In highly weathered acid soils where positively charged colloids are important, Seaman et al. (1995, 1997) determined that addition of $CaCl_2$ initially enhanced colloid mobility, likely due to release of exchangeable Al and a decrease in pH.

Soil profile development is often affected by colloid movement. Among these processes are the formation of impermeable clay layers in the subsurface and movement of Fe and Al, most probably as organic metal complexes. Moderately to strongly developed soils are generally characterized by depleted clay contents in the A horizon and larger amounts of clay generally in the upper portion of the B horizon. A substantial portion of the argillic B horizon is related to migration of clays from the upper portion of the profile and subsequent deposition (Birkeland, 1974). Flocculation in the lower part of the profile is enhanced by increased electrolyte concentration relative to the surface horizons. Clay colloid migration is evident by the presence of clay films over ped surfaces and inside voids and presence of oriented clay particles. This process is also observed in aridisols where low organic matter and elevated exchangeable Na enhance colloid transport. Clay deposition is enhanced by increasing electrolyte concentration and removal of water by evapotranspiration. In general, formation of argillic horizons requires that the soil be at least partially dry during some part of the season.

Formation of Fe- and Al-rich layers by translocation (podzolization) is probably caused by transport of metal–fulvic acid complexes, rather than movement of the dissolved metals. The spodic B horizon marks the location at which these chelates either flocculate due to increases in electrolyte concentration or by decomposition of the organic matter (Birkeland, 1974).

Ion Exchange Phenomena

Ian C. Bourg
University of California

Garrison Sposito
University of California, Berkeley

16.1 Introduction

Ion exchange phenomena involve the population of *readily exchangeable ions*, the subset of adsorbed solutes that balance the intrinsic surface charge and can be readily replaced by major background electrolyte ions (Sposito, 2008). These phenomena have occupied a central place in soil chemistry research since Way (1850) first showed that potassium uptake by soils resulted in the release of an equal quantity of moles of charge of calcium and magnesium. Ion exchange phenomena are now routinely modeled in studies of soil formation (White et al., 2005), soil reclamation (Kopittke et al., 2006), soil fertilization (Agbenin and Yakubu, 2006), colloidal dispersion/flocculation (Charlet and Tournassat, 2005), the mechanics of argillaceous media (Gajo and Loret, 2007), aquitard pore water chemistry (Tournassat et al., 2008), and groundwater (Timms and Hendry, 2007; McNab et al., 2009) and contaminant hydrology (Chatterjee et al., 2008; van Oploo et al., 2008; Serrano et al., 2009).

The prototypical chemical reaction equation for the exchange of cations A^{a+} and B^{b+} can be written as follows if X^- represents a mole of negative charge carried by the solid exchanger:

$$bX_aA_{(s)} + aB^{b+}_{(aq)} = aX_bB_{(s)} + bA^{a+}_{(aq)}. \tag{16.1}$$
Equation 16.1 can be modified in a straightforward manner to describe anion exchange reactions on positively charged surface sites. An example of Equation 16.1 of importance to sodicity and the physical properties of soils is the heterovalent Na–Ca exchange reaction:

$$2XNa_{(s)} + Ca_{(aq)}^{2+} = X_2Ca_{(s)} + 2Na_{(aq)}^+. \tag{16.2}$$
Figure 16.1 shows an experimental *ion exchange isotherm* for the binary Na–Ca exchange reaction on a montmorillonitic soil (Fletcher and Sposito, 1984a), plotted as the fractional contribution of Ca^{2+} to the total adsorbed charge of exchangeable cations ($E_{Ca} = q_{Ca}/Q$, where $q_i = z_in_i$ is the adsorbed charge of species i in mol_c kg^{-1} of solid, z_i and n_i being the valence of i and the moles of adsorbed i per kilogram of solid, respectively, and $Q = \Sigma_iq_i$) against its fractional contribution to the charge concentration of all cations in solution ($\tilde{E}_{Ca} = z_{Ca}C_{Ca}/\tilde{Q}$, where C_i is the molar concentration of species i [mol dm^{-3}] and $\tilde{Q} = \sum z_iC_i$). The convexity of the isotherm in Figure 16.1 is typical of the competitive adsorption of the higher-valence ion in heterovalent exchange reactions. As shown below, however, this convexity does not imply selectivity or thermodynamic preference of the solid exchanger for Ca^{2+} vs. Na^+.

For practical applications, ion exchange isotherms are fitted with a variety of empirical one- or two-parameter models. The most widely used one-parameter models are those introduced by Vanselow (1932), Gapon (1933), and Gaines and Thomas (1953):

$$^VK_A^B = \frac{x_B^a}{x_A^b} \frac{(A^{a+})^b}{(B^{b+})^a} \quad \text{(Vanselow)}, \tag{16.3}$$
FIGURE 16.1 Binary Na–Ca ion exchange isotherm on a montmorillonitic soil at $\tilde{Q} = 0.05\,\text{mol}_c\,\text{dm}^{-3}$ (diamonds, Fletcher et al. (1984b)) plotted as E_{Ca} vs. $\tilde{E}_{Ca}$. Nonselective isotherms were calculated for the Vanselow (thick lines) and Gapon conventions (thin lines) at $\tilde{Q} = 0.05$ and $0.5\,\text{mol}\,\text{dm}^{-3}$ (solid lines and dashed lines, respectively).

$$^{G}K_{A}^{B} = \frac{E_{B}}{E_{A}}\frac{(A^{a+})^{1/a}}{(B^{b+})^{1/b}} \quad \text{(Gapon)}, \tag{16.4}$$

$$^{GT}K_{A}^{B} = \frac{E_{B}^{a}}{E_{A}^{b}}\frac{(A^{a+})^{b}}{(B^{b+})^{a}} \quad \text{(Gaines and Thomas)}, \tag{16.5}$$

where

- ^{V}K, ^{G}K, and ^{GT}K are the Vanselow, Gapon, and Gaines–Thomas *selectivity coefficients*, respectively
- (A^{a+}) is the thermodynamic activity of A^{a+} in aqueous solution
- x_{A} is the fractional contribution of A^{a+} to the total number of moles of exchangeable cations ($x_{A} = n_{A}/\Sigma_{i}n_{i}$)

By definition, nonselective (or nonpreference) Na–Ca binary exchange isotherms are obtained if $^{V}K = 1$, $^{G}K = 1$, or $^{GT}K = 1$; examples are plotted in Figure 16.1 for $\tilde{Q} = 0.05\,\text{mol}\,\text{dm}^{-3}$ (solid lines) and $\tilde{Q} = 0.5\,\text{mol}\,\text{dm}^{-3}$ (dashed lines). Clearly, despite its name, nonselective exchange can differ among models and produce a strong, $\tilde{Q}$-dependent adsorption of the higher-valence ion; caution should therefore be used in assigning underlying mechanistic significance to isotherm shapes or selectivity coefficient values.

The most popular two-parameter model is the Rothmund–Kornfeld type model, in which the ratio of solute activities in Equations 16.3 through 16.5 is raised to a fitted power n (Bond, 1995). The Rothmund–Kornfeld model based on Equation 16.3, for example, is (Bond, 1995):

$$^{VRK}K_{A}^{B} = \frac{x_{B}^{a}}{x_{A}^{b}}\left[\frac{(A^{a+})^{b}}{(B^{b+})^{a}}\right]^{n}. \tag{16.6}$$

16.2 Surface Charge and Ion Exchange Capacities

As noted above, ion exchange phenomena involve adsorption reactions that balance the intrinsic surface charge of soil particles. The intrinsic surface charge density σ_{in} ($\text{mol}_c\,\text{kg}^{-1}$) is the sum of the net structural surface charge density σ_0 ($\text{mol}\,\text{kg}^{-1}$) and the net proton surface charge density σ_H ($\text{mol}\,\text{kg}^{-1}$) (Sposito, 1998, 2008):

$$\sigma_{in} \equiv \sigma_0 + \sigma_H. \tag{16.7}$$

The net structural ("permanent") surface charge density σ_0 results from crystalline defects, such as isomorphic substitutions of Si(IV), Al(III), or Mg(II) by lower-valence cations in 2:1 phyllosilicates (smectites, vermiculites, illites, and micas; Figure 16.2a); for these 2:1 phyllosilicates, σ_0 contributes dominantly to σ_{in} and is invariably negative. The net proton ("variable") surface charge density σ_H (the difference between the moles of protons and the moles of hydroxide ions complexed by surface functional groups ($\sigma_H = q_H - q_{OH}$)) results from Brønsted acid surface groups with a pH-dependent charge, such as hydroxyl, carboxyl, or phenol groups (Figure 16.2b); it is predominant in natural organic matter, kaolinite, and oxide minerals and can be negative, zero, or positive depending on pH, ionic strength, and other conditions.

Charge balance at solid–water interfaces imposes that Δq, the sum of the adsorbed ion charge densities q_i of all species except surface-complexed H^+ and OH^- ions, equals the opposite of the intrinsic surface charge density (Sposito, 1998, 2008):

$$\sigma_0 + \sigma_H + \Delta q = 0. \tag{16.8}$$

The net adsorbed ion charge Δq can be expressed as a sum of the net charge of ions adsorbed in the Stern layer (σ_S) (ions immobile on timescales >10 ps [Sposito et al., 1999]) or in the diffuse ion swarm (σ_d). The Stern layer charge component can be further divided into the contributions of inner-sphere (σ_{IS}) and outer-sphere (σ_{OS}) surface complexes (formed by direct contact of surface functional groups or through one or more interposed water molecules, respectively) to yield the expression (Sposito, 1998, 2008):

$$\Delta q = \sigma_{IS} + \sigma_{OS} + \sigma_d. \tag{16.9}$$

The utility of Equation 16.9 depends on the extent to which the molecular-scale coordination of adsorbed ions can be determined. Equations 16.7 and 16.8 show that σ_{in} and Δq can vary significantly with pH, ionic strength, and other variables that influence σ_H, especially in soils with low permanent structural charge (i.e., soils poor in 2:1 phyllosilicates). Experimental data on Δq vs. σ_H for a kaolinitic tropical soil suspended in
FIGURE 16.2 Major types of ion exchange sites in natural materials: (a) clay siloxane surfaces located near a site of isomorphic substitution (shown only as the basal surface O atoms (matte gray) and tetrahedral sheet Si atoms (shiny gray) of two stacked smectite lamellae with a K^+ ion (black, forming an inner-sphere surface complex) and nearby water molecules in the interlayer space. (From Sposito, G., N.T. Skipper, R. Sutton, S.-H. Park, A.K. Soper, and J.A. Greathouse. 1999. Surface geochemistry of the clay minerals. Proc. Natl. Acad. Sci. U. S. A. 96:3358–3364. Copyright 1999 National Academy of Sciences, U.S.A.) (b) pH-dependent sites resulting from the deprotonation of Lewis acid groups on organic matter or mineral oxide surfaces (here three carboxyl groups of natural organic matter (with O atoms in matte gray) coordinating an almost completely desolvated Ca^{2+} ion (central dark gray atom)). (From Sutton, R., G. Sposito, M.S. Diallo, and H.-R. Schulten. 2005. Molecular simulation of a model of dissolved organic matter. Environ. Toxicol. Chem. 24:1902–1911. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. With permission.)

LiCl solutions of varying ionic strength and pH (Figure 16.3) confirm the inverse relationship between Δq and σ_H in Equation 16.8 and the strong dependence of intrinsic surface charge density on experimental conditions. Thus, measured ion exchange isotherms and Q values for such variable-charge soils may be highly sensitive to pH and other conditions that determine σ_H.

The pH dependence of surface charge is characterized by points of zero charge, pH values at which one or more of the surface charge components in Equations 16.8 and 16.9 vanishes at fixed temperature, applied pressure, and aqueous solution composition (Sposito, 1998, 2008). For example, the pH value at which $\sigma_{in} = 0$ (where adsorbed cation and anion charge densities are equal according to Equations 16.7 and 16.8) is the point of zero net charge (p.z.n.c.). Nomenclature for these points of zero charge is listed in Table 16.1. Unfortunately, previous terminology for the points of zero charge has been highly erratic (e.g., both the p.z.s.e. and the p.z.n.c. have been termed points of zero charge, while the p.z.n.p.c. has been termed zero point of charge). Furthermore, the points of zero charge frequently have been indirectly determined from experimental data on electrophoretic mobility or particle flocculation (calculations sensitive

FIGURE 16.3 "Chorover plot" (Chorover and Sposito, 1995) of the net adsorbed ion charge against the net proton surface charge density for a Brazilian oxisol (Manaus soil). The combined data, for ionic strengths of 0.001 (open circles), 0.005 (crosses), and 0.01 (filled circles) mol kg^{-1}, can be fit to the regression equation (solid line): $\Delta q = -1.01(\pm 0.07)\sigma_H + 12.5(\pm 0.8)$, where Δq and σ_H are in mmol$_c$ kg^{-1}. Charge balance is confirmed by the values of the slope and both intercepts ($\sigma_0 = 12.5 \pm 0.4$ mmol$_c$ kg^{-1} in direct measurement). (From *Geochim. Cosmochim. Acta*, 59, Chorover, J. and Sposito, G., Surface charge characteristics of kaolinitic tropical soils, 875–884, Copyright 1995, with permission from Elsevier.)

TABLE 16.1 Points of Zero Charge

Symbol	Name	Definition
p.z.n.c.	Point of zero net charge	$\sigma_{in} = 0$
p.z.n.p.c.	Point of zero net proton charge	$\sigma_H = 0$
p.z.c.	Point of zero charge	$\sigma_p = 0$[a]
p.z.s.e.	Point of zero salt effect	$\partial\sigma_H/\partial I = 0$

[a] σ_p ($\equiv \sigma_0 + \sigma_H + \sigma_{IS} + \sigma_{OS}$) is the net particle surface charge density.

TABLE 16.2 Typical Cation Exchange Capacities (CEC, in mol_c kg^{-1}) of Soils and Major Soil Constituents

Solid	CEC
Soils	0.01–1.4
Natural organic matter	0.8–10[a]
Vermiculite	1.6–2.5
Smectite	0.7–1.7
Illite	0.2
Mica	0.1
Kaolinite	<0.05

[a] Increasing with pH and in the order peat < humic acid.

to the assumed distribution and mobility of ions in the electrical double layer [Fair and Anderson, 1989; Hunter, 1993]) or from acid–base titrations of solid suspensions (calculations that often use untested assumptions on the initial value of the net proton surface charge [Sposito, 1998; Bourg et al., 2007]).

If all adsorbed ions (except surface-complexed H^+ and OH^-) are readily exchangeable, then Δq = CEC − AEC, where CEC is the cation exchange capacity (equal to Q plus the usually small positive equivalent adsorbed charge contributed by anion exclusion from the vicinity of X^- surface sites [Sposito, 2008]) and AEC is the anion exchange capacity (defined equivalently for anion exchange on positively charged surface functional groups). Ranges of the CEC of soils and soil constituents are listed in Table 16.2. The AEC of soils is usually less than 0.05 mol_c kg^{-1} (Sposito, 2008). Major contributors to the CEC of soils are the widely studied smectite clay minerals (Sposito et al., 1999; Sposito, 2008) and the less well-characterized soil organic matter (Helling et al., 1964; Curtin et al., 1998; Sutton and Sposito, 2005; Sposito, 2008). Micaceous minerals (illite, mica) also play an important role in the uptake of small quantities of weakly solvated ions, such as K^+, NH_4^+, and Cs^+ (Maes and Cremers, 1986; Bradbury and Baeyens, 2000).

16.3 Ion Exchange Thermodynamics

If Equation 16.1 describes a true chemical equilibrium and the exchanger sites X^- are all identical (or are taken to represent an average site), a thermodynamic equilibrium constant or exchange equilibrium coefficient ^{ex}K can be defined with the relation (Sposito, 1994):

$$^{ex}K_A^B = \frac{(X_bB)^a(A^{a+})^b}{(X_aA)^b(B^{b+})^a},$$ (16.10)

where (i) represents the thermodynamic activity of species i. The equilibrium constant ^{ex}K is directly related to the difference between the standard-state chemical potentials $\mu^0[\ldots]$ of the products and reactants in Equation 16.1, termed the standard Gibbs energy change of the reaction:

$$\Delta_r G^0 = -RT \ln{^{ex}K_A^B} = a\mu^0[X_bB] + b\mu^0[A^{a+}] - b\mu^0[X_aA] - a\mu^0[B^{b+}],$$

where

 R is the molar gas constant
 T is the absolute temperature

The equilibrium chemical potentials μ of reactants and products typically differ from their standard-state values μ^0, and this difference must enter Equation 16.10 through the thermodynamic activities on its right side. For the aqueous species A^{a+} and B^{b+}, the activity is defined by setting

$$(i) \equiv \gamma_i C_i,$$ (16.11)

where γ_i is an activity coefficient (dm^{-3} mol), commonly expressed relative to the infinite dilution reference state at $T = 298.15\,K$ and $P = 1\,atm$ with the semiempirical Davies equation (Sposito, 1994):

$$\ln\gamma_i = -0.512z_i^2\left\{\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right\} \quad (I < 0.5\,mol\,dm^{-3})$$ (16.12)

where I is the ionic strength ($I = 1/2\sum_i z_i^2 C_i$). For adsorbed species, if the exchanger phase is pictured as analogous to a solid solution of two components X_aA and X_bB, an appropriate model of thermodynamic activity should be (Argersinger et al., 1950; Sposito, 1994)

$$(i) \equiv f_i x_i,$$ (16.13)

where the rational activity coefficient f_i (dimensionless) is equal to 1 in the conventionally chosen reference state $x_i = 1$, $I = 0$, $T = 298.15\,K$, and $P = 1\,atm$ (Gaines and Thomas, 1953; Sposito, 1994). No model for f_i of similar applicability and simplicity to Equation 16.12 currently exists for f_i. However, Equations 16.3, 16.10, and 16.13, and the Gibbs–Duhem relation at fixed T, P $[x_A d\ln f_A + x_B d\ln f_B = 0]$ yield closed-form expressions for calculating ^{ex}K and f_i from experimental ion exchange isotherms at fixed $\tilde{Q}$ (Argersinger et al., 1950; Sposito, 1994):

$$\ln{^{ex}K_A^B} = \int_0^1 \ln{^V K_A^B}\, dE_B,$$ (16.14)

$$b\ln f_A = E_B \ln{^V K_A^B} - \int_0^{E_B} \ln{^V K_A^B}\, dE_B.$$ (16.15)

In the context of the solid-solution picture, the A–B exchange is defined as *ideal* if $f_A = f_B = 1$, that is, if $^VK_A^B = {}^{ex}K_A^B$, and *nonpreference* if $^{ex}K_A^B = 1$. The Vanselow model in Equation 16.3 therefore describes ideal binary exchange and the nonselective isotherms with $^VK = 1$ in Figure 16.1 are *ideal thermodynamic nonpreference isotherms*. Binary exchange ^{ex}K values should obey the "triangle rule": $c \log {}^{ex}K_A^B + a \log {}^{ex}K_B^C + b \log {}^{ex}K_C^A = 0$, as has been verified within ±0.1 log units for montmorillonite (Lewis and Thomas, 1963; Gast, 1969), vermiculite (Wild and Keay, 1964), and illite (Brouwer et al., 1983).

Since the reference state for surface species includes the ionic strength condition $I = 0$, Equations 16.14 and 16.15 are strictly valid only if applied to $^VK_A^B$ vs. E_B data measured at several $\tilde{Q}$ values and then extrapolated to $\tilde{Q} = 0$ (Gaines and Thomas, 1953). In practice, this extrapolation is rarely done, but ^VK values for exchange reactions on smectites and soils have been shown to have a rather small $\tilde{Q}$-dependence (≤0.1 log units) if $\tilde{Q} \le 0.2 \, mol_c \, dm^{-3}$ (Laudelout et al., 1972; Jensen and Babcock, 1973). Furthermore, the rational activity coefficients f_i calculated with Equation 16.15 are strictly valid only for the binary systems in which they were measured; expressions for f_i in ternary or more complex exchange systems are much more complicated (Chu and Sposito, 1981; Sposito, 1994). However, several models of comparable accuracy have been proposed for estimating ternary-system activity coefficients from binary ion exchange isotherm data (Bond and Verburg, 1997).

16.4 Trends in ^VK and ^{ex}K

Broad syntheses of ion exchange data for natural materials are scarce, despite the large number of reported experimental studies. This scarcity results in part from the complexity of soils. Even for smectite minerals (the most widely studied soil constituent), analyses of ion exchange data are complicated by the difficulty of isolating these clays (exchangeable cation homogenization and removal of carbonate, organic matter, and Al and Fe hydroxide impurities require a careful choice of sample pretreatment and storage procedures [Duc et al., 2005]) and of accurately calculating the selectivity coefficient (^VK calculated without measuring C_i and q_i for all competing ions may be highly imprecise [Pabalan and Bertetti, 1999]). In addition, the measured selectivity coefficients may vary with experimental conditions, such as $\tilde{Q}$, pH, solid–liquid ratio m_s, or type of background anion because of poorly understood processes, such as ion-pair adsorption (Sposito et al., 1983a, 1983b; Griffoen and Appelo, 1993; Charlet and Tournassat, 2005), adsorption on variable-charge sites on the edge surfaces of smectite lamellae (Fletcher and Sposito, 1989; Chen and Hayes, 1999), or the influence of experimental conditions on exchanger structure (Laird and Shang, 1997).

In this section, we summarize current knowledge of the ion exchange selectivity of smectites, micaceous minerals, and soils based on reported ^VK and ^{ex}K values. In the case of smectites, we base our analysis as much as possible on studies that (1) used solid pretreatment practices known to produce pure, homoionic

materials (a series of several acid washes [pH ≈ 4], exchangeable cation homogenization [$I ≈ 1$ M], and rinsing steps followed by storage in liquid water at low temperature [Duc et al., 2005; Bourg et al., 2007]), and (2) measured q_i and C_i for all competing ions (Table 16.3). For the sake of brevity, we focus on results obtained at $T ≈ 298$ K and do not discuss the temperature dependence of ^VK or the estimation of enthalpic and entropic contributions to the Gibbs energy of exchange (Gast, 1972; Maes and Cremers, 1978; Morel et al., 2007).

16.4.1 Smectites

Ion exchange reactions on smectites that involve only strongly hydrated cations (Li$^+$, Na$^+$, and divalent metal cations M^{2+}) have ^VK values that display no hysteresis (Verburg and Baveye, 1994) and are independent of E_i within 0.1 log units (Gast, 1969; Sposito et al., 1981, 1983a, 1983b, 1983c; Tang and Sparks, 1993; Zhang and Sparks, 1996), that is, they are *ideal* within experimental precision. (Erroneous reports of "nonideal" heterovalent exchange reactions have been based on plots of $^{GT}K_A^B$ vs. E_B [Banin, 1968; Keren, 1979; McBride, 1980]; for example, the significant dependence of $^{GT}K_{Na}^M$ on E_M [M = Cu, Cu, Ni, or Zn] observed for montmorillonite is in fact consistent with an ideal exchange reaction since $^VK_{Na}^M$ is independent of E_M [Sposito and Mattigod, 1979].) Exchange reactions between strongly hydrated cations are mildly selective (i.e., slightly favor the adsorption of cations of larger ionic radius or larger valence) and weakly affected by the type of smectite (Table 16.4). As expected from the near ideality and weak selectivity of cation exchange reactions on smectites in the absence of weakly hydrated ions, chemical speciation in such systems can be reasonably well described using log $K_V ≈ 0$ for all ion exchange reactions, for example, the systems Na–H (Tournassat et al., 2004), Na–Cd, and Na–UO$_2$–UO$_2$(OH)–(UO$_2$)$_3$(OH)$_5$ (Zachara and McKinley, 1993).

Binary reactions that involve at least one weakly hydrated cation (K$^+$, NH$_4^+$, Rb$^+$, Cs$^+$, large organic cations, and, to a smaller extent, Ba^{2+}) are typically *nonideal*, and they frequently display hysteresis (Verburg and Baveye, 1994; Laird and Shang, 1997; Chatterjee et al., 2008) along with a strong dependence of ^VK on E_i (Gast, 1969; Maes and Cremers, 1978; McBride, 1979; Shainberg et al., 1987; Amrhein and Suarez, 1991), especially if the exchanging cations have very different hydration energies. This nonideality may result in part (but not entirely [Maes and Cremers, 1978; Laird and Shang, 1997]) from the greater selectivity of *octahedral-charge sites* vs. *tetrahedral-charge sites* (i.e., sites resulting from isomorphic substitutions in the octahedral or tetrahedral sheet, respectively, of phyllosilicate minerals) for weakly hydrated cations (Xu and Harsh, 1992; Onodera et al., 1998). Among alkali metals and organic cations, the adsorption selectivity of weakly hydrated cations increases with ionic radius (Gast, 1972; Maes and Cremers, 1986; Teppen and Aggarwal, 2007) because larger, less strongly hydrated ions have lower affinity for the aqueous solution phase (Mizutani et al., 1995; Teppen and Miller, 2006; Teppen and Aggarwal, 2007). Selectivity also increases

TABLE 16.3   Compilation of the Best Available Data Sets on Cation Exchange on Smectite Clay Minerals

Reference	Solid	Cations	Comments
Gast (1972)	Arizona montmorillonite	Na–Li, Na–K, Na–Rb, and Na–Cs	$\tilde{Q} = 1\,\mathrm{mmol_c\,dm^{-3}}$ (Cl$^-$ electrolyte); $T = 298\,\mathrm{K}$; m_s *not specified*; q_i *values not measured*
Maes and Cremers (1977)	Otay and RCCB[a] montmorillonites	Na–Ca	$\tilde{Q} = 10\,\mathrm{mmol_c\,dm^{-3}}$ (Cl$^-$ electrolyte); $T = 298\,\mathrm{K}$; $m_s \approx 10\,\mathrm{g\,kg^{-1}}$; q_i *values not measured*
Maes and Cremers (1978)	Otay and RCCB montmorillonites, hectorite	Na–Cs	$\tilde{Q} = 10\,\mathrm{mmol\,dm^{-3}}$ (Cl$^-$ electrolyte); $T = 298\,\mathrm{K}$; m_s *not specified*; pH = 5.5–6; *clay stored in freeze-dried form*; q_i *values not measured*
Sposito et al. (1981)	Wyoming montmorillonite	Na–Cu	$\tilde{Q} = 10\,\mathrm{mmol_c\,dm^{-3}}$ (Cl$^-$ or ClO$_4^-$ electrolytes); $T = 298\,\mathrm{K}$; $m_s = 13$–$21\,\mathrm{g\,kg^{-1}}$; pH = 5–6 to avoid Cu adsorption on oxide-type edge surface sites
Sposito et al. (1983a, 1983b, 1983c)	Wyoming montmorillonite	Na–Ca, Na–Mg, Ca–Mg, and Na–Ca–Mg	$\tilde{Q} = 50\,\mathrm{mmol_c\,dm^{-3}}$ (Cl$^-$ or ClO$_4^-$ electrolytes); $T = 298\,\mathrm{K}$; $m_s = 20$–$30\,\mathrm{g\,kg^{-1}}$; pH = 6.8–7.1
Xu and Harsh (1992)	Cameron montmorillonite	Na–Li, Na–K, Na–Rb, and Na–Cs	$\tilde{Q} = 10\,\mathrm{mmol_c\,dm^{-3}}$ (Cl$^-$ electrolyte); $T = 298\,\mathrm{K}$; m_s *not specified*; C_i and q_i *values not reported*; ^VK *values reported only at* $E_{Na} = 0.5$
Tang and Sparks (1993)	Wyoming montmorillonite	Na–Ca and K–Ca	$I = 10\,\mathrm{mmol\,dm^{-3}}$ (Cl$^-$ electrolyte); $T = 296\,\mathrm{K}$; $m_s = 10.2\,\mathrm{g\,dm^{-3}}$; pH = 6.8; *clay stored in freeze-dried form*
Zhang and Sparks (1996)	Wyoming montmorillonite	Na–Cu	$\tilde{Q} = 20\,\mathrm{mmol\,dm^{-3}}$ (ClO$_4^-$, Cl$^-$, NO$_3^-$, or SO$_4^{2-}$ electrolyte); $T = 298\,\mathrm{K}$; $m_s \approx 16$–$17\,\mathrm{g\,dm^{-3}}$; pH = 5.2–6.5, *decreasing with* q_{Cu}; *clay stored in freeze-dried form*
Laird and Shang (1997)	Synthetic fluorohectorite	Mg–Ba	$\tilde{Q} = 20\,\mathrm{mmol\,dm^{-3}}$ (Cl$^-$ electrolyte); T = room temperature; $m_s = 10\,\mathrm{g\,dm^{-3}}$; no acid wash, but the material (a synthetic magnesium silicate) should not contain Al or Fe hydroxides or organic impurities; *clay stored in freeze-dried form*
Charlet and Tournassat (2005)	Wyoming montmorillonite	Na–Fe(II), Ca–Fe(II), Na–Ca–Fe(II)	$\tilde{Q} = 50$ or $130\,\mathrm{mmol_c\,dm^{-3}}$ (Cl$^-$ electrolyte); T *not specified*; $m_s = 4$–$8\,\mathrm{g\,dm^{-3}}$; pH = 2.1–3.6 to avoid Fe adsorption on oxide-type edge surface sites; q_{Fe} *not measured (estimated by mass balance)*

[a] RCCB montmorillonite: reduced-charge Camp-Berteau (Morocco) montmorillonite. Layer charge was reduced by 5%–41% using the Hofmann–Klemen effect (Maes and Cremers, 1977, 1978).

The studies by Gast (1972) and Maes and Cremers (1977, 1978) are tentatively included, despite the fact that they did not include measurements of q_i values, because of the good quality of their pretreatment methods. Studies that used smectites stored by freeze-drying also are tentatively included, although storage in liquid water at low temperature is preferred (Duc et al., 2005). Experimental procedures that may adversely affect the quality of experimental results are reported in italics in the last column.

with surface charge density (Gast, 1972; Maes and Cremers, 1978; Shainberg et al., 1987; Xu and Harsh, 1992) (Table 16.4) and perhaps especially with the charge density of octahedral-charge sites (Xu and Harsh, 1992).

Metal–ligand complexes also can adsorb by ion exchange, but this process has not been deeply studied. The strong adsorption of copper-ethylenediamine complexes $\mathrm{Cu(en)_2^{2+}}$ (Maes and Cremers, 1986) and the complexation of nitroaromatic compound with exchangeable cations on smectite surfaces (Chatterjee et al., 2008) are consistent with the expectation that metal–organic complexes should have an affinity similar to large organic cations for smectite surfaces. Divalent metals are known to coadsorb with anions, such as Cl$^-$ (Sposito et al., 1983a, 1983b; Charlet and Tournassat, 2005) or HCO$_3^-$ (Griffoen and Appelo, 1993), but the mechanism of this coadsorption (ion-pair formation or diffuse layer process) and its dependence on experimental conditions are not well understood (Sposito, 1991).

16.4.2 Micaceous Minerals

Illites and micas have a lamellar morphology similar to that of smectites but with collapsed, K$^+$-filled interlayers (Sposito, 2008).

The reactivity of external basal surfaces of illite and mica crystals is thought to be similar to that of smectites (Brouwer et al., 1983), but the crystals also carry a small population of sites (0.1%–10%) with a very high affinity for weakly hydrated cations (K$^+$, NH$_4^+$, Rb$^+$, and Cs$^+$) (Brouwer et al., 1983; Thellier and Sposito, 1989; Liu et al., 2004; Tournassat et al., 2007). These so-called *frayed-edge sites* occur at partially propped-open, K$^+$-depleted edges of collapsed interlayers (Rajec et al., 1999; McKinley et al., 2004). Adsorption on frayed-edge sites may be determined to a certain extent by nonequilibrium processes, such as diffusion-controlled adsorption over timescales of weeks or more (Comans et al., 1991). Such processes can cause difficulties in defining and measuring ion exchange selectivity, since the population of "accessible" frayed-edge sites may vary with time, experimental conditions, the type of exchangeable cation, and the choice of agent used to extract adsorbed cations for measuring q_i (Brouwer et al., 1983; Comans et al., 1991; Baeyens and Bradbury, 2004; Tournassat et al., 2007). Nevertheless, the finding that frayed-edge sites obey the "triangle rule" (Brouwer et al., 1983) suggests that ion exchange on these sites can be reasonably well described on certain timescales as a thermodynamic process. If ion B = K, Rb, or Cs, experimental $^VK_A^B$ values decrease sharply with E_B

TABLE 16.4 Recommended Values for ^VK on Smectite Based on the Studies Listed in Table 16.3

Variable	log K	References
Exchanges of two strongly hydrated cations		
$^VK_{Na}^{Li}$	-0.08 ± 0.06	Gast (1972), Xu and Harsh (1992)
$^VK_{Na}^{M(II)}$	0.11 ± 0.11^a (M = Mg, Ca, and Cu)	Maes and Cremers (1977), Sposito et al. (1981, 1983a), Tang and Sparks (1993), Zhang and Sparks (1996)
$^VK_{Mg}^{Ca}$	0.01 ± 0.02 (E_{Na} = 0, 0.016, or 0.036)	Sposito et al. (1983b, 1983c)
$^VK_{Fe(II)}^{Ca}$	~0.01	Charlet and Tournassat (2005)[b]
Exchanges involving at least one weakly hydrated cation		
$^{ex}K_{Na}^{K}$	0.58 ± 0.14^c	Gast (1972), Xu and Harsh (1992)
$^{ex}K_{Na}^{Rb}$	1.08 ± 0.25^c	Gast (1972), Xu and Harsh (1992)
$^{ex}K_{Na}^{Cs}$	$1.23 \times CEC - 0.06^d$	Gast (1972), Maes and Cremers (1978), Xu and Harsh (1992)
$^VK_{Mg}^{Ba}$	~0.5 in the three-layer hydrate, increasing to ~1.4 in the two-layer hydrate	Laird and Shang (1997)

Confidence intervals calculated as $\pm 2\sigma$ where several ^VK values were available.

[a] Neglecting Na–Ca exchange data obtained with reduced-charge montmorillonites, which show $^VK_{Na}^{Ca}$ values closer to 0 (Maes and Cremers, 1977).

[b] Charlet and Tournassat (2005) erroneously reported their ^{GT}K values as ^VK values, but for homoionic Ca–Fe(II) exchange $^{GT}K = {}^VK$.

[c] log $^{ex}K_{Na}^{K}$ and log $^{ex}K_{Na}^{Rb}$ are thought to increase with Q (Shainberg et al., 1987; Xu and Harsh, 1992).

[d] Linear regression with $r^2 = 0.91$, $p < 0.001$; CEC = 0.66–$1.44 \, mol_c \, kg^{-1}$, estimated from the number of octahedral and tetrahedral substitutions in the clay unit cell formula.

when the frayed-edge sites become B-saturated (Brouwer et al., 1983), a behavior that can be described with a two- or three-site model, that is, one or two types of highly selective frayed-edge site plus weakly selective basal surface sites (Maes and Cremers, 1986; Liu et al., 2004; Tournassat et al., 2007).

16.4.3 Soils and Sediments

For highly heterogeneous, multiphase media such as soils and sediments, Equations 16.14 and 16.15 have no clear thermodynamic meaning and any selectivity model may be suitable on a case-by-case basis. For example, the Gapon selectivity coefficient has been found to be less variable than ^VK over broad ranges of exchanger phase composition for Na–Ca, Mg–K, and Ca–K exchange reactions in some soils (Naylor and Overstreet, 1969; Jensen and Babcock, 1973; Evangelou and Coale, 1987; Feigenbaum et al., 1991; Agbenin and Yakubu, 2006). Experimental data on log $^VK_{Ca}^{M}$ vs. E_M (M = Na, K, or Mg) obtained for a range of conditions of pH, $\tilde{Q}$, and soil type illustrate the variability of the ion exchange selectivities of soils (Figure 16.4). The scatter of log $^VK_{Ca}^{Na}$ values at $E_{Na} \leq 0.2$ in Figure 16.4b may reflect in part the high sensitivity of ^VK at small E_i values to sources of error such as the dissolution of soil materials (Carlson and Buchanan, 1973; Sheta et al., 1981).

Despite the inherent complexity of soil and sediment ion exchange properties, these have been modeled conceptually with some success assuming their exchange properties result from their smectite constituent (Charlet and Tournassat, 2005) or from the sum of their smectite, organic matter (Curtin et al., 1998), and/or micaceous constituents (Bradbury and Baeyens, 2000).

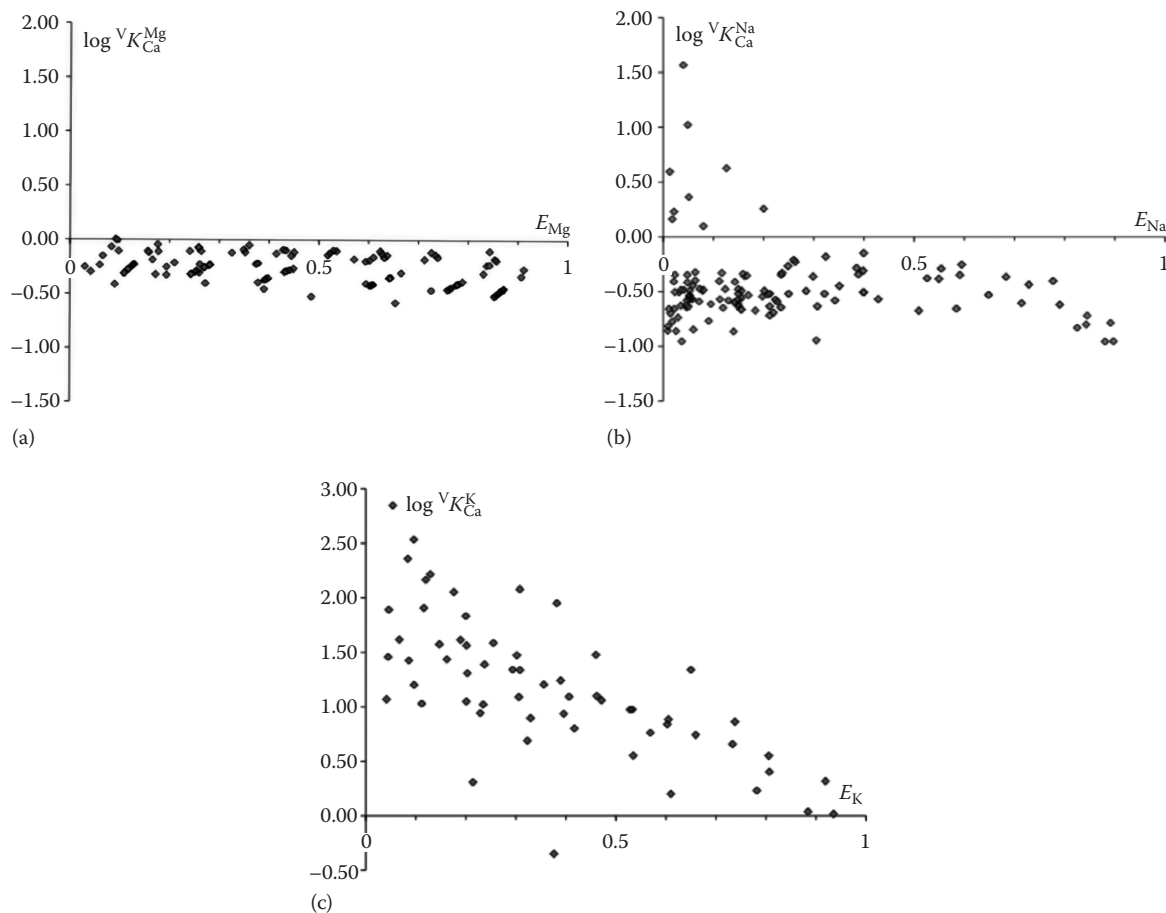
The first type of approximation is exemplified by the ion exchange properties of Amazon river suspended matter in the system Na–K–Ca–Mg, which are essentially identical to those of montmorillonite, even though only half of the CEC of the suspended matter originates from its clay-size fraction (Charlet and Tournassat, 2005). The second type of approximation is well illustrated by the fact that the Mg–Ca exchange selectivity of soils is correlated with their ratio of organic carbon to clay content (Curtin et al., 1998). Curtin et al. (1998) successfully described the Mg–Ca selectivity of several soils with a two-site model where the soil organic matter and clay fractions were represented by log $^VK_{Mg}^{Ca}$ = 0.6 and 0.1, respectively. Similar additive behavior of soil smectites and soil organic matter has been used to interpret the ion exchange selectivity of montmorillonitic soils in the system Na–Ca–Mg (Fletcher et al., 1984a; Sposito and Fletcher, 1985) and may also explain the Ca–Sr selectivity of soils (Juo and Barber, 1969) and the Ca–Cd and Ca–Zn selectivity of acidic soils (Voegelin and Kretzschmar, 2003). Additive behavior of micaceous materials and other soil constituents may explain the strong adsorption of K^+ and Cs^+ at low E_K or E_{Cs} values in numerous soils and sediments (Feigenbaum et al., 1991; Bradbury and Baeyens, 2000; Sinanis et al., 2003; Liu et al., 2004; Agbenin and Yakubu, 2006). The concept that soil ion exchange selectivity is a sum of the selectivities of component phases evidently can be quite powerful (Sposito and Fletcher, 1985; Curtin et al., 1998; Bradbury and Baeyens, 2000; Charlet and Tournassat, 2005), although it neglects nonadditive behavior such as the enhanced (about 0.3 log unit greater) Na–Ca selectivity of smectites when their interlayers contain Al-hydroxide polymers (Keren, 1979; Janssen et al., 2003).


FIGURE 16.4 Compilation of experimental data on $\log {}^{V}K_{Ca}^{M}$ vs. E_M (M = Mg^{2+}, Na^+, or K^+) in soils if $\tilde{Q} \leq 0.2$ mol dm^{-3} and $T = 298$ K; (a) $\log {}^{V}K_{Ca}^{Mg}$ data for a loam soil (Jensen and Babcock, 1973), calcareous clay soils (Van Bladel and Gheyi, 1980), smectitic soils with 27–96 g kg^{-1} organic carbon (Curtin et al., 1998), and a montmorillonitic soil (DeSutter et al., 2006); (b) $\log {}^{V}K_{Ca}^{Na}$ for a montmorillonitic soil (Fletcher et al., 1984b), kaolinitic soils (Levy et al., 1988), a kaolinitic sandy loam soil with 25.7 g kg^{-1} organic carbon (Rhue and Mansell, 1988), a calcareous, smectitic clay soil (Amrhein and Suarez, 1991), and an illite–kaolinite clay soil (Bond, 1995); (c) $\log {}^{V}K_{Ca}^{K}$ for a loam soil (Jensen and Babcock, 1973), kaolinitic soils (Levy et al., 1988), a kaolinitic sandy loam soil with 25.7 g kg^{-1} organic carbon (Rhue and Mansell, 1988), an illite–kaolinite clay soil (Bond, 1995), and a tropical soil (Agbenin and Yakubu, 2006).

16.5 Ion Exchange and Chemical Speciation Models

Analytical solutions of thermodynamic equations to determine exchanger phase composition rapidly become intractable in systems that involve more than three exchangeable ions (Bond and Verburg, 1997). For such complex systems, a numerical solution can be implemented in chemical speciation models after dividing Equation 16.1 into two hypothetical half-reactions involving a fictitious anionic species X^- (Sposito and Mattigod, 1977; Shaviv and Mattigod, 1985; Fletcher and Sposito, 1989):

$$aX^- + A_{(aq)}^{a+} = X_aA_{(s)}, \tag{16.16a}$$

$$bX^- + B_{(aq)}^{b+} = X_bB_{(s)}. \tag{16.16b}$$
Equation 16.16 can be incorporated into conventional chemical speciation models using its analogy with surface complexation or solid-solution reactions, as described below.

16.5.1 Modeling Ion Exchange as a Surface Complexation Process

Most chemical speciation programs include a model of surface complexation reactions (similar in form to Equation 16.16) where the thermodynamic activities of uncharged surface species arbitrarily are set equal to their concentrations $[X_i i]$ (Sposito, 2004). On this model, the half-reaction selectivity coefficients associated with Equation 16.16 are the following (Fletcher and Sposito, 1989; Stadler and Schindler, 1993):

$$^{half}K^A = \frac{[X_aA]}{(X^-)^a(A^{a+})}, \tag{16.17a}$$

$$^{\text{half}}K^{\text{B}} = \frac{[\text{X}_{\text{b}}\text{B}]}{(\text{X}^-)^{\text{b}}(\text{B}^{\text{b}+})}. \tag{16.17b}$$

Equation 16.17 can be incorporated into any program that models surface complexation reactions; typically, $^{\text{half}}K$ is set to a very large value (10^{10}–10^{20}) for a reference cation, such that the wholly uncomplexed X^- sites contribute negligibly to the total mass balance on X, and the $^{\text{half}}K$ values of other cations are chosen to fit experimental equilibrium constants (Flechter and Sposito, 1989; Stadler and Schindler, 1993). Certain chemical speciation programs include a specific model of ion exchange reactions based on Equation 16.17. For example, in the program PHREEQC2 (Appelo and Postma, 2005), the fictitious species X^- is excluded from the total mass balance on X and Na^+ is chosen as a reference species with log $^{\text{half}}K^{\text{Na}} = 0$. Suggested values of $^{\text{half}}K$ for other cations on smectite are provided in the PREEQC2 database (Appelo and Postma, 2005). The use of Equation 16.17 with fixed $^{\text{half}}K$ values corresponds to an implicit assumption that $^{\text{GT}}K$ is equal to an equilibrium constant, since $^{\text{GT}}K$ and $^{\text{half}}K$ are related through

$$^{\text{GT}}K_{\text{A}}^{\text{B}} = \left[\frac{(^{\text{half}}K^{\text{B}})^{\text{a}}}{(^{\text{half}}K^{\text{A}})^{\text{b}}}\right]\left(\frac{\text{b}^{\text{a}}}{\text{a}^{\text{b}}}\right)Q^{(\text{b}-\text{a})}. \tag{16.18}$$

Equation 16.17 has been used to model ion exchange reactions involving protons, alkali metals, trace metals, and actinides on clay minerals (Stadler and Schindler, 1993; Zachara and McKinley, 1993; Poinssot et al., 1999; Bradbury and Baeyens 2000, 2005, 2009; Baeyens and Bradbury, 2004; Charlet and Tournassat, 2005; Heidmann et al., 2005; Bourg et al., 2007; Gu and Evans, 2008). Most of these studies (with the notable exception of Charlet and Tournassat, 2005) investigated systems where $^{\text{half}}K$ should be constant if ion exchange is ideal, either because the main background electrolyte cation was $\text{A}^{\text{a}+}$ and occupied most ion exchange sites, such that $^{\text{GT}}K_{\text{A}}^{\text{B}} \oplus {}^{\text{V}}K_{\text{A}}^{\text{B}}(\text{b/a})^{\text{a}}$, or because the system studied was homovalent, in which case $^{\text{GT}}K_{\text{A}}^{\text{B}} = {}^{\text{V}}K_{\text{A}}^{\text{B}}$.

16.5.2 Modeling Ion Exchange as a Solid-Solution Process

Some chemical speciation programs include a model of solid-solution formation, which is also similar in form to Equation 16.16. The "solubility coefficients" associated with Equation 16.16 are described as follows in the solid-solution formalism (Appelo and Postma, 2005):

$$^{\text{solubility}}K^{\text{A}} = \frac{(\text{X}^-)^{\text{a}}(\text{A}^{\text{a}+})}{x_{\text{A}}f_{\text{A}}}, \tag{16.19a}$$

$$^{\text{solubility}}K^{\text{B}} = \frac{(\text{X}^-)^{\text{b}}(\text{B}^{\text{b}+})}{x_{\text{B}}f_{\text{B}}}. \tag{16.19b}$$

where (X^-) is the activity of a fictitious dissolved species. In the program PHREEQC2, Equation 16.19 can be solved by defining X^-, $\text{A}^{\text{a}+}$, and $\text{B}^{\text{b}+}$ as dissolved species and $\text{X}_{\text{a}}\text{A}$ and $\text{X}_{\text{b}}\text{B}$ as solid phases and by setting $^{\text{solubility}}K \ll 1$ for a chosen reference cation, such that X^- contributes negligibly to the mass balance on X. If $f_{\text{A}} = f_{\text{B}} = 1$, Equation 16.19 is identical to the Vanselow model with

$$^{\text{V}}K_{\text{A}}^{\text{B}} = \left[\frac{(^{\text{solubility}}K^{\text{B}})^{\text{a}}}{(^{\text{solubility}}K^{\text{A}})^{\text{b}}}\right]. \tag{16.20}$$

The ideality of ion exchange reactions between strongly hydrated cations on smectite (Table 16.4) suggests that Equation 16.19 may be more accurate than Equation 16.17 for multicomponent ion exchange reactions on smectite over broad ranges of exchanger phase composition. However, to our knowledge, Equation 16.19 has never been used for this purpose.

16.6 Micro- and Nanoscale Perspectives on Ion Exchange Selectivity

Micro- and nanoscale studies have yielded insight into the processes that determine $^{\text{V}}K$ using theoretical estimates of long-range electrostatic forces (Barak, 1989; Rytwo et al., 1996), short-range interactions (Shainberg and Kemper, 1966; Eberl, 1980), or statistical mechanical quantities (Sposito, 1993; Benjamin, 2002). In the present chapter, we focus on two subfields illustrating micro- and nanoscale studies: (1) the molecular-scale coordination and dynamics of exchangeable ions and (2) the influence of exchanger microstructure on ion exchange selectivity.

16.6.1 Molecular-Scale Coordination and Dynamics of Exchangeable Ions

Spectroscopic and molecular simulation methods have been widely used to probe the coordination environment and dynamics of exchangeable cations in smectites (Sposito and Prost, 1982; Sposito, 2004; Skipper et al., 2006) and have been increasingly applied to other exchanger phases (Skipper et al., 1995; Kim and Kirkpatrick, 1998; Schlegel et al., 2006; Xu et al., 2006). Spectroscopic techniques can probe the molecular structure of the interface as a function of distance from a solid surface (by x-ray reflectivity [Schlegel et al., 2006; Park et al., 2008]), the dynamics of water H atoms (by quasielastic neutron scattering [QENS] [Marry et al., 2008]), the local coordination environment of certain atomic probes (such as water or Li by neutron diffraction with isotopic substitution [NDIS] [Skipper et al., 1995; Powell et al., 1998] or Co, Sr, Pb, Cu, Cs, and other atoms by x-ray absorption spectroscopy [XAS] [Papelis and Hayes, 1996; Chen and Hayes, 1999; Strawn and Sparks, 1999; Morton et al., 2001; Bostick et al., 2002]), the coordination environment and

rotational dynamics of paramagnetic atoms such as Cu (by electron spin resonance [ESR] or electron spin-echo modulation [ESEM] [McBride et al., 1975; Brown and Kevan, 1988]), and the local molecular environment ("chemical shielding") of atoms with an odd number of nucleons or protons such as ^{23}Na, ^{133}Cs, ^{113}Cd, or ^{35}Cl (by nuclear magnetic resonance [NMR] [Weiss et al., 1990; Kim and Kirkpatrick, 1998; Xu et al., 2006]). Molecular simulation techniques, primarily Monte Carlo (MC) and molecular dynamics (MD), have been used for over a decade to complement spectroscopic results (Chang et al., 1995; Park and Sposito, 2002). Most spectroscopic and simulation studies have been used to probe homoionic exchangers, but a few studies have investigated the behavior of a "reporter" cation doped into a smectite that is almost homoionic in another cation (McBride et al., 1975; Brown and Kevan, 1988; Marry and Turq, 2003; Bourg and Sposito, 2010).

Spectroscopic and molecular simulation studies have shown that the aqueous phase in smectite interlayers is analogous to a concentrated ionic solution (Sposito and Prost, 1982; Powell et al., 1998); in the two- and three-layer hydrates and on external basal surfaces, it diffuses about 30%–40% as fast as bulk liquid water (Chang et al., 1997; Marry et al., 2008; Bourg and Sposito, 2010). Exchangeable cations in smectite one-layer hydrates form inner-sphere surface complexes (ISSC) for obvious steric reasons, and they diffuse very slowly (McBride et al., 1975; Chang et al., 1995, 1997; Bourg and Sposito, 2010); at higher hydration levels, they can be divided into three categories based on their interaction with smectite surfaces: divalent metal cations (M^{2+}), strongly hydrated alkali metal cations (Li^+, Na^+), and weakly hydrated cations (K^+, Rb^+, Cs^+). The divalent cations are adsorbed in fully solvated form as outer-sphere surface complexes (OSSC) or in the diffuse layer (DL) (McBride et al., 1975; Brown and Kevan, 1988; Papelis and Hayes, 1996; Chen and Hayes, 1999; Strawn and Sparks, 1999; Greathouse et al., 2000; Chávez-Páez et al., 2001; Morton et al., 2001; Whitley and Smith, 2004); they tumble and diffuse slowly, about 1%–10% as fast as in bulk water (McBride et al., 1975; Brown and Kevan, 1988; Greathouse et al., 2000; Bourg and Sposito, 2010). The strongly hydrated monovalent cations (Li^+, Na^+) also adsorb as OSSC or DL species on octahedral-charge sites, but they form inner-sphere surface complexes (ISSC) on tetrahedral-charge sites (Chang et al., 1995, 1997; Leote de Carvalho and Skipper, 2001; Marry and Turq, 2003; Marry et al., 2003; Tambach et al., 2004, 2006; Greathouse and Cygan, 2005); they diffuse about 20%–60% as fast as in bulk water if adsorbed on octahedral-charge sites, but are essentially immobile (on subnanosecond timescales) on tetrahedral-charge sites (Chang et al., 1995, 1997; Leote de Carvalho and Skipper, 2001; Marry and Turq, 2003; Bourg and Sposito, 2010). Finally, the weakly hydrated cations form primarily ISSC on smectite surfaces along with small amounts of OSSC or DL species (Chang et al., 1998; Nakano et al., 2003; Whitley and Smith, 2004; Tambach et al., 2006; Liu et al., 2008); two populations of ISSC exist in Cs- and K-smectite interlayers that may correspond to cations located above ditrigonal cavities or "triads" of O atoms of the siloxane surface (Weiss et al., 1990; Onodera

et al., 1998; Park and Sposito, 2002; Nakano et al., 2003); the mobility of these cations along smectite basal surfaces is not well characterized (Kosakowski et al., 2008), but recent results suggest that they diffuse only 5%–8% as fast as in bulk liquid water (Bourg and Sposito, 2010). Clearly, the molecular-scale behavior of cations on smectites parallels their ion exchange selectivity: The strongly hydrated cations (M^{2+}, Li^+, Na^+) adsorb mainly as fully solvated OSSC or DL species and display ideal, weakly selective ion exchange behavior, whereas the weakly hydrated ions adsorb mainly as ISSC and display nonideal, strongly selective ion exchange behavior. The ISSC formed by Li^+ and Na^+ on tetrahedral-charge sites do not fit this simple classification, suggesting that Li^+ and Na^+ may show nonideal exchange behavior on smectites with high tetrahedral charge. This point may not have been noticed previously because reference smectites typically carry 80% ± 20% octahedral-charge sites (Xu and Harsh, 1992).

Thanks to increases in computational capabilities, MD and MC simulations may soon be able to "bridge the gap" from the time and length scales (or number of MC simulation steps) required to probe molecular exchanger phase structure and dynamics (<1 ns and ≤1 nm) to the time and length scales (tens of nanoseconds and nanometers) on which ion exchange equilibria become established (Greathouse and Cygan, 2005; Rotenberg et al., 2007). Molecular simulation methods could then be used to test Equation 16.13 directly or to predict ^{V}K values (Greathouse and Cygan, 2005; Teppen and Miller, 2006). Teppen and Miller (2006) showed that the Gibbs energy difference between K-, Rb-, and Cs-montmorillonite (one component of the Gibbs energy of exchange) at fixed interlayer spacing and interlayer water content could be determined by MD simulation. Greathouse and Cygan (2005) found that ten 1 ns MD simulations of a 4 nm thick Na^+–UO_2^{2+}–CO_3^{2-} aqueous solution on a montmorillonite basal surface were too short and small scale to determine ^{V}K accurately, but were sufficient to identify important processes, such as the formation of $\left[Na_2UO_2(CO_3)_3\right]^{2-}$ complexes.

16.6.2 Coupling between Cation Exchange and Exchanger Structure

As pointed out above, Equation 16.10 has strict thermodynamic meaning only if all exchanger sites X^- are identical. For smectites (Sposito, 1992; Laird and Shang, 1997) and natural organic matter (Sutton et al., 2005), however, the microstructure of the exchanger phase depends on experimental conditions and, therefore, the X^- may *not* be identical at different points along a binary exchange isotherm, or even in different regions of the exchanger phase within a single sample. In the case of smectite clay minerals, the stacking arrangement of smectite lamellae (number of layers per stack, interlayer spacing) is a dynamic, nonuniform property (several interlayer hydration levels may coexist [Tamura et al., 2000; Wilson et al., 2004; Ferrage et al., 2005]), which depends on the magnitude and location of clay structural charge (Slade et al., 1991; Tambach et al., 2004), the

population of adsorbed cations (Schramm and Kwak, 1982; Sposito, 1992; Laird and Shang, 1997; Ferrage et al., 2005; Table 16.5), the thermodynamic activity of water (Norrish, 1954; Slade et al., 1991; Laird et al., 1995), as well as the previous history of the clay (Verburg and Baveye, 1994; Laird et al., 1995; Chatterjee et al., 2008) and its degree of compaction (Kozaki et al., 1998). Molecular-scale simulations confirm that homoionic montmorillonites frequently exhibit several stable states of crystalline swelling separated by energy barriers (Whitley and Smith, 2004; Tambach et al., 2004, 2006; Smith et al., 2006). Transitions between these states are predominantly enthalpic (Whitley and Smith, 2004), driven by cationic solvation energy (Whitley and Smith, 2004)—as opposed to being determined by the hydrogen bond network of interlayer water (Tambach et al., 2006)—strongly hysteretic (Tambach et al., 2006), and in fact thermodynamically analogous to a phase transition (Laird and Shang, 1997; Whitley and Smith, 2004).

The stacking arrangement, in turn, determines the fraction of X^- sites located on external vs. internal basal surfaces, which may
FIGURE 16.5 Conceptual model of the feedback between the ion exchange selectivity (^VK), population of exchangeable ions (E_i), and arrangement of clay particles (interlayer spacing, number of layers per stack) in smectite clay minerals. (Reproduced from Laird, D.A., and C. Shang. 1997. Relationship between cation exchange selectivity and crystalline swelling in expanding 2:1 phyllosilicates. Clays Clay Miner. 45:681–689. With permission of The Clay Minerals Society, publisher of *Clays and Clay Minerals*.)

TABLE 16.5 Interlayer Hydration Level (Norrish, 1954; Laird and Shang, 1997; Chatterjee et al., 2008) and Number of Lamellae per Stack (Sposito, 1992; Verburg and Baveye, 1994; Verburg et al., 1995) in Dilute Aqueous Suspensions of Homoionic Montmorillonite

Cation	Hydration Level[a]	Lamellae per Stack
Li^+	>3	1.0
Na^+	>3	1.0–1.7
K^+	2	1.0–7.0
Cs^+	1–2	1.4–4.0
Mg^{2+}	3	2.7–14.0
Ca^{2+}	3	3.0–20.0
Ba^{2+}	2–3	2.7–7.0

[a] Number of statistical water monolayers in each smectite interlayer.

have unequal cation exchange selectivities (Keren, 1979; Sposito et al., 1983a), and the fraction of internal-surface X^- sites in contact with one-, two- or three-layer interlayer hydrates, which also may have unequal cation exchange selectivities (Barak, 1989; Laird and Shang, 1997; Van Loon and Glaus, 2008). Thus, cation exchange on swelling clay minerals involves a feedback loop among adsorption, exchanger structure, and selectivity (Laird and Shang, 1997; Figure 16.5) that is reminiscent of the behavior of certain ion-selective pores (Kuyucak et al., 2001). This feedback loop may explain the occurrence of exchangeable cation "de-mixing" (Shainberg and Otoh, 1968; Fink et al., 1971; Iwasaki and Watanabe, 1988), increased selectivity for the preferred cation at high surface loading of the same cation (Shainberg et al., 1980; Laird and Shang, 1997; Janssen et al., 2003), cation exchange hysteresis (Fripiat et al., 1965; Verburg et al., 1995), and increased selectivity for weakly hydrated ions as smectite charge density increases (Maes and Cremers, 1978; Shainberg et al., 1987). Smectite ^{ex}K values would then have thermodynamic meaning only if defined for a certain particle arrangement (Laird and Shang, 1997). Thus, the nonideality of cation exchange reactions that involve weakly hydrated cations may be related to the fact that these cations cause a sequential collapse of the interlayer from a three-layer hydrate or more (for Li^+, Na^+, and strongly hydrated divalent cations M^{2+}) to a two-layer hydrate (for K^+ and Ba^{2+}) to a one-layer hydrate (for Cs^+; Table 16.5).

Chemisorption and Precipitation Reactions

Robert G. Ford
*United States Environmental
Protection Agency*

17.1 Introduction

The partitioning of dissolved components to a solid surface in soils is governed by the competition between sorption and desorption reactions. Chemisorption (or chemical adsorption) of a dissolved component (adsorbate) to a solid surface (adsorbent) has been defined as "adsorption that results from chemical bond formation (strong interaction) between the adsorbent and the adsorbate in a monolayer on the surface" (IUPAC, 1997). These partitioning reactions may be influenced by electrostatic forces between the adsorbate and adsorbent, similar to those controlling ion-exchange reactions (discussed in this volume). It has also been observed that sorption of solution species may result in more than monolayer coverage at the surface of solid surfaces. In these cases, the adsorbate may form polynuclear surface complexes or surface precipitates (e.g., Scheidegger and Sparks, 1996). Surface precipitation can be considered as a special form of homogeneous precipitation reaction where a solid component in the soil participates in the overall reaction process (Chapter 7 in Stumm and Morgan, 1996). In the following discussion, surface precipitation includes all processes that result in incorporation of the sorbate into a solid structure that could not form in the absence of the adsorbent. This includes (1) formation of a dilute solid solution with a structure that is distinct from or shared with the original adsorbent, (2) epitaxial growth of a new solid phase sharing a structural relationship with the adsorbent, and (3) nucleation of a new solid phase at the solid–water interface. Background information and discussion of the literature (dating up to 1998) addressing chemisorption and precipitation reactions in soils were provided by McBride (1999). The following discussion provides an update on the current understanding of these reactions in soil systems.

17.2 Conceptual Distinctions in Chemisorption and Precipitation

17.2.1 Chemisorption

Chemisorption reactions involving formation of mononuclear chemical bond between solutes in the solid solution and reactive surfaces in solid matrix are referred to as *surface complexation* reactions and are typically categorized by the relative binding strength of interaction between the adsorbate (species in solution) and the adsorbent (soil solid). One should note that the conceptual underpinning that guides our historical and contemporary understanding of chemisorption/surface complexation reactions is the notion that reactive surface sites can be viewed as a special type of ligand that coordinates to cations or exchanges with anions from solution (Schindler et al., 1976; Sigg and Stumm, 1981; Sposito, 1998, 1999). While our molecular-level understanding of the physicochemical forces that govern the characteristics of these surface reactions has improved over the years, the underlying conceptual basis remains technically sound. The driving force for molecules or ions in soil solution to form surface complexes with sites of adsorption in the soil solid matrix is governed by the physical and chemical properties of the adsorbate, sorption sites, and the soil solution (i.e., "solute," "sorbent," and "solvent" in the more general terminology in Stumm [1992]). As an example, the probability that a cation will form an inner-sphere versus an outer-sphere surface complex will, in part, be governed by the relative free-energy change between the cation maintaining a water molecule versus a surface hydroxyl site within its immediate coordination sphere. Cations for which coordination with a water molecule is more energetically favorable will tend to favor outer-sphere surface complexes.

However, the overall tendency for surface complex formation will be governed by other factors such as electrostatic forces between the adsorbate and sorption site. Therefore, projecting trends in surface complex formation must be predicated on knowledge of the physicochemical properties of the three primary components in the reaction (i.e., adsorbate, sorption sites, and solvent), in addition to how the surface complexation reaction(s) may be modified by interactions of any or all of these primary components with other solution or solid components in the reaction system.

There are several recent discussions that provide useful perspective on the fundamental chemical factors that govern the extent for and relative strength of surface complex bond formation (e.g., Sverjensky, 2006; Brown, 2009). It should be noted that current developments in our understanding of the physicochemical forces controlling chemisorption reactions have benefited from exploration of the molecular-level processes controlling ion partitioning onto soil solids, as reflected in discussions of bond formation by Sverjensky (2006) and Brown (2009). This emphasis is, to some extent, a departure from past efforts to relate apparent trends in ion partitioning based on periodic properties of the elements (i.e., adsorbate), for example, reference to apparent macroscopic trends with respect to qualitative concepts such as the "lyotropic" or "Hofmeister" series. However, as noted in several studies, deviations in observed ion partitioning trends from qualitative concepts specific to the sorbate support the need to further development of our molecular-level understanding of chemisorption reactions (e.g., Dove and Craven, 2005; Teppen and Miller, 2006; Rotenberg et al., 2009; Kowacz et al., 2010). (Another form of solid-solution partitioning, hydrophobic bonding, plays an important role in governing uptake of nonpolar organic compounds onto soil solids. This specific partitioning mechanism is not discussed further within this chapter, and the reader is referred to other comprehensive reviews [e.g., Karickhoff, 1981; Stumm, 1992; Schwarzenbach et al., 1993], along with recent developments in the concept of bonding mechanisms intermediate between nonspecific (hydrophobic) bonding and chemisorption reactions for organic molecules [e.g., Lambert, 2008; Keiluweit and Kleber, 2009].)

There is a range of binding strength for ion adsorption that depends on characteristics of the adsorbate, adsorbent, and chemistry of the soil solution. However, discussions of binding strength are generally couched in terms of "weak" or "strong" surface complexation reactions, albeit a common convention in chemistry would categorize both the covalent and electrostatic interactions involved in adsorption as "strong" intermolecular forces (Israelachvili, 1994). For description of surface complexation reactions, the microscopic distinction that the adsorbate possesses solvation properties is borrowed from the characterization of soluble ion pairs (Westall, 1986; Stumm, 1992). If solvating water molecules are interposed between the cation or anion and the surface, the surface complex is referred to as *outer sphere* and is considered to be "weak." Conversely, if upon surface complexation, the adsorbate loses waters of hydration such that there are no water molecules interposed between the cation

or anion and the surface, the surface complex is referred to as *inner sphere* and is considered to be "strong" (Sposito, 1984). The propensity of a cation or anion to form either an inner-sphere or outer-sphere surface complex is a function of the adsorbate, the surface functional groups of the adsorbent, and the aqueous-phase chemistry (e.g., pH and ionic strength).

For inner-sphere complexation of ions onto solid surfaces, the molecular rationale for the reaction is formation of covalent bonding within an ion's first coordination sphere. From this perspective, several authors have observed an apparent consistency between the approach to establish linear free-energy relationships (LFER) for aqueous coordination reactions and surface complexation reactions developed for the formation of surface complexes (e.g., Schindler et al., 1976; Sigg and Stumm, 1981; Tamura and Furuichi, 1997). The apparent systematic correlation captured in an LFER reflects the relationship between the free energies of complex formation and thermodynamic properties of ions. For surface complexation reactions, LFER plots of the stability constants of metal complexation with hydroxyl surface sites versus the hydrolysis constant for metals in aqueous solutions have been interpreted as providing a thermodynamic basis for the apparent selectivity trends for metal adsorption onto reference hydrous metal oxides. Recent compilations by Bradbury and Baeyens (2005, 2009) extend these relationships to metal adsorption onto the phyllosilicate minerals, montmorillonite, and illite. As stated by the authors, the utility of these relationships is their use as a tool to estimate surface complexation constants for ions in which no data or data of high uncertainty are available. In Figure 17.1, LFER plots of published data for cations and anions are provided to illustrate the correlations that one may observe with similarities in the energetics and molecular characteristics of homogeneous (aqueous) and heterogeneous (surface) coordination reactions. While these relationships are tied to our conceptual understanding of the molecular characteristics of surface-coordination reactions, their use to project surface complexation trends in soil systems should be limited to qualitative applications. The number of interacting components, both aqueous and solid, within a soil system necessitates a more comprehensive perspective.

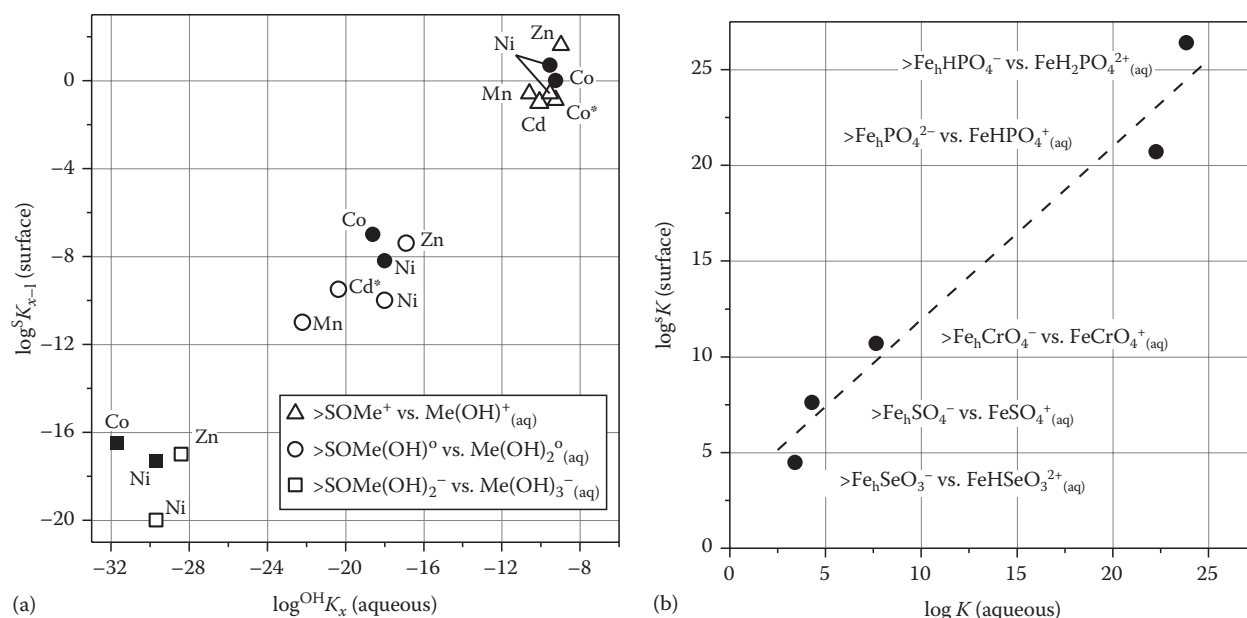
Important adsorbent phases commonly found in the environment include phyllosilicate minerals, metal-oxohydroxide phases, sulfide phases, and natural organic matter (Dixon and Schulze, 2002). Many phyllosilicate minerals possess a permanent negative charge as a result of the substitution of lower-valence cations, that is, Mg(II), Fe(II), Li(I) for Al(III) in the octahedral layer and/or Al(III) for Si(IV) in the tetrahedral layer (referred to as isomorphic substitution). There are two main classes of phyllosilicate minerals based on layer structure. The 1:1 mineral layer type is comprised of one Si-tetrahedral layer and one Al-octahedral layer, which in soils is commonly represented by the mineral kaolinite having the general formula $[Si_4]$ $Al_4O_{10}(OH)_8 \cdot nH_2O$. Kaolinite and related minerals generally have insignificant degrees of cation substitution within their octahedral and tetrahedral layers, and, thus generally posses a very low permanent negative charge. The 2:1 mineral type is


FIGURE 17.1 Comparison of related formation constants for surface and aqueous complexes for coordination reactions between a selection of ions and aqueous or surface functional groups. (a) Relationship between the stability constant for cation complexation with surface hydroxyls of Na-exchanged montmorillonite/illite versus the metal hydrolysis species formation constant in solution (Bradbury and Baeyens, 2005, 2009). Species stoichiometry noted in legend; starred metal labels indicate surface stability constant is for Ca-exchanged montmorillonite. (b) Relationship between the formation constant for anion ligand exchange with surface hydroxyls on hydrous ferric oxide versus formation of aqueous complexes with Fe^{3+} (Visual MINTEQ, 2009). Species stoichiometry shown next to data point.

comprised of one Al-octahedral layer interposed between two Si-tetrahedral layers comparable to the mica structures. The 2:1 layer class is represented by a variety of minerals, which are classified based on the location (tetrahedral versus octahedral layer) and relative amount of isomorphic substitution. The three major mineral classes within the 2:1 layer type are illite ($M_x[Si_{6.8}Al_{1.2}]$ $(Al_3Fe_{0.25}Mg_{0.75})O_{20}(OH)_4$), vermiculite ($M_x[Si_7Al](Al_3Fe_{0.5}Mg_{0.5})$ $O_{20}(OH)_4$), and smectite ($M_x[Si_8]Al_{3.2}Fe_{0.2}Mg_{0.6}O_{20}(OH)_4$), which display different levels of cation substitution in their tetrahedral and octahedral layers. The permanent negative charge imparted to 2:1 clay minerals by isomorphic substitution is typically balanced through exchange reactions involving major cations in soil solution (e.g., Na^+, K^+, Ca^{2+}, or Mg^{2+}; represented by "M_x" in the formulas listed above).

Chemisorption of ions to phyllosilicates may occur via electrostatic exchange reactions (on the basal plane or within clay particle interlayers) or surface complexation with surface functional groups, for example, terminal silanol or aluminol functional groups at the edges of clay particles, for example, montmorillonite (Bradbury and Baeyens, 2005) and illite (Bradbury and Baeyens, 2009). Due to differences in the levels of isomorphic substitution for the 1:1 and 2:1 clay-mineral classes, ion exchange is usually only significant for 2:1 phyllosilicates. In addition to siloxane oxygen atoms along the basal plane, phyllosilicates possess two types of terminal ionizable hydroxyl groups (>OH°), aluminol and silanol, protruding from the edge surface. These edge >OH° groups can form both inner- and outer-sphere surface complexes with metal cations and oxyanions depending on

the pH of the bathing solution and on the specific chemical characteristics of the adsorbate.

The most important inorganic phases for surface reactions with ions in many soil systems are the metal-oxohydroxide phases. These phases are characterized by hexagonal or cubic close-packed O or OH anions with Fe(II)/Fe(III), Al(III), and/or Mn(III)/Mn(IV) occupying octahedral sites. These oxides are present as discrete phases and as complex mineral assemblages, being associated with phyllosilicates and primary minerals as coatings or with humic macromolecules. In soils, the crystallinity of these phases typically varies from poorly ordered to well-crystalline forms and grain size from the nanometer to micrometer scale. Among the most common Fe-oxohydroxide phases found in soils are the poorly ordered phase ferrihydrite ($Fe_2O_3 \cdot nH_2O$), and the moderate to well-crystalline phases, goethite (α-FeOOH), and hematite (α-Fe_2O_3). The most common Al-oxohydroxide phase found in soils is gibbsite (γ-Al(OH)$_3$). Additionally, poorly ordered aluminosilicates can be important reactive phases in certain soils and these include the very poorly ordered allophanes (Si/Al ratios 1:2–1:1) and the paracrystalline phase, imogolite ($SiO_2 \cdot Al_2O_3 \cdot 2H_2O$). While Mn oxohydroxides are less prevalent than Fe and Al oxohydroxides in soils, they are very important phases in terms of surface-mediated redox reactions and because of their propensity for high metal sorption. The mineralogy of Mn is complicated by the range in Mn–O bond lengths resulting from extensive substitution of Mn(II) and Mn(III) for Mn(IV). Thus, there exists a continuous series of stable and metastable compositions from

MnO to MnO$_2$ forming a large variety of minerals. Among the more common Mn oxohydroxides are pyrolusite (β-MnO$_2$), the hollandite–cryptomelane family (α-MnO$_2$), todorokite, and birnessite (δ-MnO$_2$).

The reactive surface functional group for all of the metal-oxohydroxide phases is the inorganic >OH^o moiety exposed on the outer periphery of these minerals. The reactivity of a specific metal oxohydroxide is dependent on the surface area (S$_A$), surface-site density (N$_S$), the degree of coordination of the >OH^o group to the bulk structure, and the point of zero charge (PZC). The charge on the mineral surface may impose either attractive or repulsive contributions to the overall adsorption reaction, depending on the type of charge possessed by the adsorbate. The surface charge of oxohydroxide minerals and edge sites on phyllosilicates is derived from the protonation and ionization of exposed surface hydroxyl groups, represented by >OH^o, where ">" represents the bond to structural elements within the solid (e.g., Fe, Al, Mn). As a function of pH, the surface functional groups can be generally described with the following idealized nomenclature: >OH$_2^+$, >OH^o, and >O$^-$, which illustrates the pH-dependent charging behavior in the absence of other potential-determining ions in solution. The exact charge associated with the various surface functional groups is difficult to measure, so the main purpose of employing this nomenclature is to illustrate that surface charge varies as a function of soil solution chemistry. Discussions of surface-charging behavior and surface-coordination reactions for a range of common soil minerals is provided elsewhere (e.g., Stumm, 1992; Sparks, 2003). The properties of the adsorbent that impact surface complexation are controlled by both the grain size and specific chemical structure of the solid phase.

While the surfaces of oxohydroxide minerals constitute a significant fraction of sites that participate in chemisorption reactions, they are not the only type of surface sites present. Depending on soil type and mineralogy, other sources of reactive surfaces may include carbonates, sulfides, and soil organic matter. For these solids, the same conceptual convention can be employed to identify the reactive chemical surface moiety for the purpose of describing chemisorption reactions based on chemical and electrostatic properties. There are several published examples that illustrate application of the surface complexation model (SCM) concept to describe ion chemisorption to the surface of carbonates (Villegas-Jimenez et al., 2009), sulfides (Wolthers et al., 2005), and components of soil organic matter (Westall et al., 1995; Cabaniss, 2008; Cabaniss, 2009). Summarized in Table 17.1 is a listing of the types of chemical nomenclature used to represent the reactive surface sites for these solid components.

Soil organic matter, or humus, is derived from the physical, chemical, and biological breakdown of vegetation and fauna originating from above and below the soil surface (e.g., Wershaw, 1994; Zech et al., 1997; Ponge, 2003; Sutton and Sposito, 2005). The recalcitrant soil organic matter thus produced is comprised of complex polymers called humic substances, which constitute another very important reactive phase in soil solids

TABLE 17.1 Published Examples for Chemical Representations of Reactive Surface Sites Used in Development of Surface Complexation Models to Describe Protonation–Deprotonation Reactions for Variably Charged Solids

Chemical Representations of Reactive Surface Sites	
Chemical System	Protonation–Deprotonation Reactions
CaCO$_3$ (calcite)–H$_2$O–CO$_2$	>CaOH^o + H$^+$ = >CaOH$_2^+$

	>Fe$_3$SH^o + H$^+$ = >Fe$_3$SH$_2^+$
	>Fe$_3$SH^o = >Fe$_3$S$^-$ + H$^+$
Lignocellulosic substrate–H$_2$O	>S$_1$OH = >S$_1$O$^-$ + H$^+$ (carboxylic sites)
(Ravat et al., 2000)	>S$_2$OH = >S$_2$O$^-$ + H$^+$ (phenolic sites)
FIGURE 17.2 Hypothetical structural model of a soil organic matter structural fragment illustrating types of reactive functional groups. Protonation–deprotonation reactions occurring during acid titration are generally attributed to carboxylic and phenolic moieties.

(e.g., Kelleher and Simpson, 2006; Simpson et al., 2007a, 2007b; Smejkalova and Piccolo, 2008). A variety of functional groups are present in humic substances, and, like >OH^o functional groups of the inorganic metal oxohydroxides, these also are characterized by pH-dependent charging mechanisms. The primary functional groups associated with humic substances in terms of surface charge are typically represented as carboxyl and phenolic groups (Figure 17.2); however, less abundant amino, imidazole, sulfhydryl, or other potential structural groups may play an important role in protonation–deprotonation and chemisorption reactions of some ions when present at trace levels (e.g., Schaumann, 2006; Niederer et al., 2007; Matynia et al., 2010). Degradation of natural organic matter in soils leads to a change in the relative distribution of the chemical structures within the complex suite of macromolecular compounds that constitute

soil organic matter. As an example, Lorenz et al. (2007) illustrate a general scheme for the evolution of the chemical makeup of terrestrial biomass during weathering resulting in the depletion of oxygenated-alkyl carbon structures and the enhancement of alkyl carbon structures. As illustrated in the review by Chefetz and Xing (2009), changes in the relative proportion of structural components in soil organic matter may influence the reactivity of this adsorbent pool within soils, since these structural components comprise the reactive moieties in soil organic matter that are binding sites for dissolved inorganic and organic compounds in the soil solution.

As illustrated by the previous discussion, chemical bonding between solutes in the soil solution and the surfaces of soil solids will exert control over solute concentrations. Typically, these reactions dominate solid-water partitioning at low solute concentrations or in systems where there is minimal active precipitation of new soil minerals. However, some soil systems will be characterized by large fluxes of ions through the soil pore water either due to infiltration from external water sources or internal instability of the mineral matrix as a function of soil age (e.g., Huggett, 1998; Lilienfein et al., 2003) or microbial activity (e.g., Wiederhold et al., 2007). In these systems, active precipitation of new solid phases may dominate over chemisorption reactions to control solute concentrations in the soil solution.

17.2.2 Precipitation and Coprecipitation

Mineral–water reactions occur during movement of water through soil pores. These reactions may result in the release of structural components from soil solids due to mineral dissolution or result in the buildup to oversaturation and consequent precipitation of secondary minerals. As an outcome of mineral–water reactions along a flow path, fluid compositions and the mineralogical makeup of the soil matrix will continuously evolve toward a stable state or an equilibrium state. Mineral precipitation processes in soil systems may govern the concentrations of major and trace elements in the soil solution.

Full treatment of precipitation processes, including coverage of relevant thermodynamic and kinetic concepts, is outside the scope of this document. The reader is referred to numerous standard textbooks in geochemistry, soil science, and aquatic chemistry (e.g., Lindsay, 1979; Drever, 1982; Stumm, 1992; McBride, 1994; Stumm and Morgan, 1996; Langmuir, 1997; Lasaga, 1999; Sparks, 2003; Sposito, 2008). The purpose of this section is to introduce key concepts and issues regarding the potential impact precipitation reactions may exert on solute partitioning in soils. In general, mineral precipitation in relation to the solid-phase partitioning of soil solutes can be discussed in the context of four widely studied processes:

- *Precipitation from solution*: Nucleation and growth of a solid phase exhibiting a molecular unit that repeats itself in three dimensions. Homogeneous nucleation occurs from bulk solution and heterogeneous nucleation occurs on the surfaces of organic or mineral particles. Heterogeneous nucleation is thought to be more important in natural systems that are rich in reactive inorganic and biological surfaces. Precipitation may result in the formation of sparingly soluble oxohydroxides, carbonates, and, in anoxic systems, sulfides. Many precipitation reactions have a strong dependence on pH.

- *Coprecipitation*: Incorporation of an element as a trace or minor constituent within a precipitating phase. In this case, the ion substitutes for a more concentrated component in the crystal lattice (isomorphous substitution). This process is distinct from adsorption due to incorporation of the ion within the bulk structure of the major mineral phase. Examples of coprecipitation include Cr(III) in hydrous ferric oxide, Cd(II) in calcium carbonate, and As(III) in iron sulfide.

- *Surface precipitation*: A precipitation process intermediate between surface complexation and precipitation from bulk solution. Surface precipitation represents the continuous growth of particles formed via heterogeneous nucleation. Macroscopic studies of adsorption of some solutes, particularly divalent and trivalent cations, suggest that precipitation occurs at surfaces under conditions where the solid is apparently undersaturated based on solution concentrations (Dzombak and Morel, 1990).

- *Mineral transformation*: Adsorbed ions can become incorporated into minerals that form as a result of recrystallization or mineral transformation processes in soils. Transformation reactions may be accelerated or retarded by the ion, and in some cases mineral transformation may result in the exclusion of the solute from the solid phase. Examples include incorporation of anions, such as As(V) and U(VI), into metastable hydrous ferric oxide (poorly crystalline ferrihydrite) and transformation to more crystalline Fe oxohydroxides (e.g., Ford, 2002; Nico et al., 2009), coprecipitation of metals with iron monosulfide and transformation to iron disulfide (e.g., Lowers et al., 2007), and incorporation of metals into layered double hydroxides (LDHs; typically with Al) as intermediates between adsorbed/surface precipitated metal ions like Ni and Zn and metal-ion-containing phyllosilicates.

The relative importance of these processes will be determined by solute characteristics as well as characteristics of soil solution and solids within a given system. These individual processes are discussed in more detail in the following sections.

17.2.2.1 Precipitation from Solution

Solution precipitation or crystallization can be divided into two main processes: nucleation and crystal growth. Nucleation occurs prior to growth of a mineral crystal. Both nucleation and growth processes require a system to be oversaturated in the new phase. The probability that nucleation will occur increases exponentially as a function of the degree of oversaturation. Nucleation of a new phase is often facilitated in the presence of

a surface (heterogeneous nucleation) rather than in bulk solution (homogeneous nucleation). Because nucleation and growth are processes that compete for dissolved solutes, at high degrees of oversaturation, the rate of nucleation may be so fast that all excess solute is partitioned into crystal nuclei. In contrast, lower levels of oversaturation can result in the growth of existing crystals without nucleation. Well-formed or euhedral crystals typically develop slowly via growth from solution at low degrees of oversaturation. During crystal growth, various chemical reactions can occur at the surface of the growing mineral, such as adsorption, ion exchange, diffusion, and formation of surface precipitates. In general, the rate of crystal growth is controlled either by transport of solutes to the growing surface (i.e., transport controlled), by reactions at the surface (i.e., surface controlled), or a combination of these factors.

For the most abundant cations present in soils, such as Al, Si, Fe, Mn, Ca, and Mg, precipitation of mineral forms is common and will in many cases control concentrations observed in solution (e.g., see Chapter 5 in Sposito, 2008). Concentrations of trace solutes are typically several orders of magnitude below the concentrations of the major ions in soil solutions. At low concentrations, adsorption, surface precipitation, or formation of a dilute solid solution (coprecipitation; e.g., Shao et al., 2009) may be the more probable removal processes for trace solutes (McBride, 1994).

17.2.2.2 Continuum from Surface Complexation to Precipitation

Experimental studies examining chemisorption at high solute concentrations have been used to illustrate that surface loadings can exceed monolayer coverages (Dzombak and Morel, 1990). Surface precipitation may result when adsorption leads to high sorbate coverage at the mineral–water interface. Surface precipitation can be thought of as an intermediate stage between surface complexation and bulk precipitation of the sorbing ion in solution (Farley et al., 1985; Katz and Hayes, 1995; Lützenkirchen and Behra, 1995). At low concentrations of the sorbing metal at the mineral surface, surface complexation is the dominant process. As the concentration of the sorbate increases, the surface complexation concentration increases to the point where nucleation and growth of a surface precipitate occurs. Surface precipitation can be viewed as a special case of coprecipitation, where the mineral interface is a mixing zone for ions incorporated into the surface precipitate and those from the underlying substrate (e.g., Thompson et al., 1999; Schlegel et al., 2001; Román-Ross et al., 2006; Schlegel and Manceau, 2006). It is generally believed that surface precipitation can occur from solutions that would appear to be undersaturated relative to precipitate formation based on considering solution saturation indices. The reasons for this may be due, in part, to incomplete consideration of all possible precipitate phases with lower solubility that could form under system conditions or to the way component activities at the mineral–water interface are modeled (Kulik, 2002a, 2002b; Sverjensky, 2003).

Characterization of metal partitioning in soils developed under a variety of conditions have confirmed the importance of the interfacial precipitation products identified in simple experimental systems (e.g., Manceau et al., 2000; Jacquat et al., 2008). However, it is unclear if these phases were formed via homogeneous or heterogeneous reactions in the observed soil systems. With improvements in the availability of solubility and thermochemical data for solids that were previously unidentified in soil systems, it may become apparent that their formation can be assumed as a more common feature of solute partitioning. It should be noted, however, that solid surfaces do play significant roles as collectors of solutes into a more confined reaction volume and they often serve as the primary source of soluble components that combine with solutes to form precipitation products.

17.3 Influence of Abiotic and Biotic Processes

The chemical characteristics of the soil solution and properties of soil mineral components are, in part, influenced by microbial reactions (e.g., Brown et al., 1999; Chadwick and Chorover, 2001; Birkham et al., 2007). Microbial activity within the soil system may also play a more direct role in controlling ion speciation and mobility via direct respiration of solutes in soil pore water or adsorbed to mineral surfaces (e.g., Lloyd et al., 2003). The influence of microbial reactions may be more pronounced in soils with large pools of degradable organic carbon and supporting nutrient fluxes. For microbially productive soil systems, soil-solution chemical parameters such as pH, alkalinity, and the concentrations of iron, manganese, and sulfur species may be regulated, in part, by microbial respiration. As an example, microbial respiration within the rhizosphere impacts the level of CO_2 in the soil solution, with resultant CO_2 partial pressure 10- to 100-fold higher than that of the atmosphere (Hinsinger et al., 2009). Ultimately, the soil solution chemistry will be governed by the dynamic interaction between these biotic processes and concurrent chemical weathering of solid components within the soil. In order to provide perspective on the potential influence of the subsurface microbiology, the following discussion provides an overview of general characteristics of subsurface microbiology and the influence of microbial activity on the redox state within soil pore water.

Since microorganisms chemically transform soil constituents such as dissolved oxygen, iron (aqueous and solid forms of Fe(III) and Fe(II)), and sulfur (aqueous species such as sulfate and dissolved sulfide), their metabolic reactions may exert significant influence on the redox chemistry within soil pore water. As previously discussed, redox conditions within the soil may govern precipitation–dissolution reactions that control precipitation or coprecipitation of solutes, as well as the types and concentration of soil solids that may serve as adsorbents. From this perspective, some knowledge about the microbial populations that a function within the soil system may be necessary

to understand the existing redox status and make projections about how it may evolve. For heterotrophic microorganisms, the electrons or reducing equivalents (hydrogen or electron-transferring molecules) produced during degradation of organic compounds must be transferred to a terminal electron acceptor (TEA). Observations of microbial systems have led to the development of a classification system that groups microorganisms into three categories, according to predominant TEAs (Chapelle et al., 2002; Salminen et al., 2006):

- *Aerobic bacteria*: Bacteria that can only utilize molecular oxygen as a TEA. Without molecular oxygen, these bacteria are not capable of degradation.
- *Facultative aerobes/anaerobes*: Bacteria that can utilize molecular oxygen or when oxygen concentrations are low or nonexistent, may switch to nitrate, manganese oxides, or iron oxides as electron acceptors.
- *Anaerobes*: Bacteria that cannot utilize oxygen as an electron acceptor and for which oxygen is toxic. Though members may utilize nitrate or other electron acceptors, it can be said that they generally utilize sulfate or carbon dioxide as electron acceptors.

In any environment in which microbial activity occurs, there is a progression from aerobic to anaerobic conditions (ultimately methanogenic) with an associated change in the redox status of the system. There is generally a definite sequence of electron acceptors used in this progression through distinctly different redox states. The rate, type of active microbial population, and level of activity under each of these environments are controlled by several factors. These include the concentration of the electron acceptors, substrates that can be utilized by the bacteria, and specific microbial populations active within the soil system. This results in a loss of organic carbon and various electron acceptors from the system as well as a progression in the types and physiological activity of the indigenous bacteria.

If microbial activity is high, the soil system would be expected to progress rapidly through these conditions. The following scenario outlines a general sequence of events in which aerobic metabolism of preferential carbon sources would occur first. The carbon source may be from anthropogenic organic sources or other more readily degradable forms of natural organic carbon, which has entered the system previously or simultaneously with surface infiltration.

- *Oxygen-reducing to nitrate-reducing conditions*: Once available oxygen is consumed, active aerobic populations begin to shift to nitrate respiration. Denitrification will continue until available nitrate is depleted or usable carbon sources become limiting.
- *Nitrate-reducing to manganese-reducing conditions*: Once nitrate is depleted, populations that reduce manganese may dominate. Bacterial metabolism of substrates utilized by manganese-reducing populations will continue until the concentration of manganese oxide becomes limiting.

- *Manganese-reducing to iron-reducing conditions*: When manganese oxide becomes limiting, iron reduction becomes the predominant reaction mechanism. Available evidence suggests that iron reduction does not occur until all Mn(IV) oxides are depleted. In addition, bacterial Mn(IV) respiration appears to be restricted to areas where sulfate is nearly or completely absent.
- *Iron-reducing to sulfate-reducing conditions*: Iron reduction continues until substrate or carbon limitations allow sulfate-reducing bacteria (SRB) to become active. SRB then dominate until usable carbon or sulfate limitations impede their activity.
- *Sulfate-reducing to methanogenic conditions*: Once usable carbon or sulfate limitations occur, methanogenic bacteria are able to dominate.

Ultimately, these processes may govern both the chemical speciation of solutes in soil solutions and the solid-phase partitioning reactions that control aqueous solute concentrations. For the latter, biotic controls on solution chemistry could potentially dictate the types of adsorbent surfaces or the saturation state of the soil solution relative to solute precipitation reactions.

As a unique example of the biogeochemical complexity of soil systems, it is worth examining the volume of soil immediately adjacent to living roots that project down from plants located at the soil surface. This zone within the soil system is referred to as the rhizosphere, which encompasses a unique setting relative to the fluxes of chemical constituents that are governed by interactions among plant physiological processes, soil microorganisms, soil mineral components, and the transport of soil water and gases (e.g., Belnap et al., 2003; Hinsinger et al., 2009). Within the rhizosphere, plants mediate the chemical composition of the soil solution via release of low-molecular-weight organic acids such as malate, citrate, and oxalate (Jones, 1998; Bais et al., 2006). These organic acids may form complexes with ions in solution, form surface complexes with soil minerals, or may be oxidized to forms of inorganic carbon via microbial degradation (along with new biomass). Depending on the relative concentration of these low-molecular-weight organic acids to ions and sorption sites, complexation reactions that occur in these ternary systems may lead to decreased (Kraemer et al., 1999; Neubauer et al., 2000) or increased (Neubauer et al., 2000) ion adsorption onto mineral surfaces. More complex organic molecules, such as siderophores and other hydroxamic acids that are secreted by plants and microorganisms (Kraemer et al., 2006; Crumbliss and Harrington, 2009), present a more specialized class of organic molecules that can form polydentate complexes with ions in solution. These organic molecules may possess specific functional roles such as increasing the availability of nutritional forms of iron (e.g., Crumbliss and Harrington, 2009) or detoxifying metal ions present in the soil solution (e.g., Gilis et al., 1998; Dimkpa et al., 2008). Interactions of ions with these organic molecules in the soil solution exert direct influence on the potential for chemisorption or precipitation reactions to occur.

17.4 Quantitative Descriptions of Chemisorption and Precipitation Reactions

Reviews of mathematical models for describing chemisorption reactions and their practical application for depicting solute complexation to solid surfaces in natural systems is provided in Zachara and Westall (1999) and Goldberg et al. (2007 and references therein). In general, these models can be grouped into two categories that project solute partitioning using semiempirical relationships or through the development of chemical reaction expressions that depict chemisorption as the formation of chemical bonds between the solute and surface sites representing the termination of the adsorbent structure. The second category of models is commonly referred to as SCMs. Their use for describing chemisorption reactions has become standard since they provide the following: (1) the means to rationalize observed patterns in solute binding to solid surfaces due to electrostatic and chemical properties of the reactants and (2) a mathematical framework consistent with thermodynamic descriptions of aqueous complexation and precipitation reactions. The utility and chemical sensibility of this modeling framework has resulted in the development of computer software applications and supporting data compilations of chemisorption reactions for cations and anions on soil mineral phases (e.g., Dzombak and Morel, 1990; Tonkin et al., 2004). Detailed descriptions of the chemical basis and development of SCMs is available in a number of sources (e.g., Sposito, 1984; Davis and Kent, 1990; Stumm and Morgan, 1996). Brown (2009) presents an alternative framework in which to evaluate thermodynamic properties of chemisorption reactions. In this approach, the bond valence model is invoked to assess constraints on the types of surface bonds that can form. A primary constraint that is applied in this framework is the valence sum rule, which states that the sum of bond valences around any atom should be equal to the atomic valence. In contrast to the common formalism within most SCMs of providing explicit descriptions and accounting of electrostatic interactions across the surface, the bond valence model incorporates all electrostatic effects into the bonds that are formed. The extent of adhesion between atoms in the solid and solution (i.e., surface complex formation) is evaluated by ensuring that the valence sum rule is obeyed around each atom in the system. Although the bond valence model provides a way to evaluate the chemical suitability of proposed bonding structures, this approach is not currently implemented in a mathematical framework that can be merged with existing thermodynamic formalisms for calculating solution complexation and precipitation reactions. Until this occurs, the formalisms employed for describing surface bond formation in current SCMs will likely continue to be employed.

Goldberg et al. (2007) and Goldberg and Criscenti (2008) have highlighted potential limitations for the application of SCMs to project chemisorption reactions in soil systems. Reaction expressions depicting chemisorption reactions presume knowledge of the types and availability of solid surfaces in the system being modeled. The heterogeneity of soil systems hampers selection of appropriate reactive surfaces and adsorption site densities to be explicitly represented in an SCM. Two proposed modeling strategies to address this difficulty include the component additivity (CA) and general composite (GC) approaches. The CA approach is based on the summed contribution of individual adsorbent phases, and, thus, makes use of individual reaction expressions developed for each solute–adsorbent pair from model experimental systems. The predictive capability of the CA approach will be highly dependent on knowledge of the specific adsorbents active in solute chemisorption for a particular soil. The GC approach is based on the assumption that the assemblage of adsorbent phases within the soil can be represented by "generic" surface functional groups with reaction stoichiometries and formation constants derived from experimental adsorption data for individual soil samples. The utility of the GC approach over purely empirical partitioning coefficients is that the chemisorption model can be coupled to equilibrium models of aqueous solute speciation and solubility. Thus, chemisorption model projections will be sensitive to changes in aqueous solute speciation and/or solution saturation state relative to homogeneous precipitation of the solute. In addition, the GC approach allows for explicit accounting of electrostatic interactions across the surface (based on laboratory measurements of surface-charging behavior) or incorporation of these interactions implicitly within the optimized surface complexation constant determined for a given system.

Another limitation of SCMs has been the standard state used to express the activities of surface sites and surface species. Kulik (2002a, 2002b) and Sverjensky (2003) have illustrated that the hypothetical standard state employed in current model formulations results in equilibrium constants that are directly dependent on properties of the adsorbent such as the site density and surface area. Thus, surface protonation and stability constants for solute adsorption developed for a particular mineral specimen, for example, goethite, at a given solid:solution ratio may not be directly transferable to modeling adsorption of another goethite specimen with different specific surface area and/or solid:solution ratio. Both authors have proposed an alternative standard state that can be used to develop surface protonation and complex stability constants that are independent of individual adsorbent properties and experimental conditions. The new standard-state convention can be used to convert conditional stability constants derived using law-of-mass action (LMA) algorithms (Sverjensky, 2003) or the Gibbs energy minimization (GEM) approach (Kulik, 2002b). As illustrated by Kulik (2002a), surface complexation constants derived using the LMA convention can be converted to the GEM convention using the newly proposed standard state for surface species. In addition, Kulik (2002b) illustrates that the GEM approach also allows one to factor in which adsorbents are stable or metastable, and how the site types are distributed between the adsorbent surfaces. Given our understanding that the suite of mineral components, and their inherent solubility and surface complexation properties, undergoes dynamic transitions in soil systems

(e.g., Chadwick and Chorover, 2001), the GEM approach presents an attractive alternative for modeling low-temperature aqueous chemistry reactions.

A final issue of concern for modeling solute adsorption onto mineral surfaces is development of approaches to represent the transition from surface loadings less than to greater than monolayer coverage. As discussed previously, the formation of a mononuclear surface complex may represent an intermediate step to the development of a polynuclear species with 2D or 3D order, commonly referred to as surface precipitates. The composition of surface precipitates will be governed by the participating elements from the solution and the host mineral surface. Modeling strategies have been developed within the convention of the LMA-SCM (Farley et al., 1985; Katz and Hayes, 1995), and they have been employed to replicate sorption data for wide ranges of surface coverage assuming either the formation of a pure solid or solid solution incorporating the solute species (e.g., Charlet and Manceau, 1992; Román-Ross et al., 2006). For these applications, assumptions are made about the fraction of the adsorbent that participates in formation of binary or higher-order solid solutions, as well as the ideality of the modeled solid solutions relative to the endmember structures. Curti et al. (2005) and Kulik (2006) have proposed alternative strategies to represent and select the solid solutions that may realistically form based on GEM. Significant model development and testing remains before much confidence can be placed on projections of surface precipitation or surface solid–solution formation in soil systems.

17.5 Observations of Cation and Anion Solid-Phase Partitioning in Soils

The distribution of cations and anions between the solid–water interfaces present in soils is governed by chemical characteristics of the aqueous and solid species and the chemistry of the soil solution. The distribution between adsorbed and precipitated forms of these constituents will also be influenced by the total concentrations of reactive species, as well as the influence of biotic processes that govern the distributions of redox-sensitive reactants within the soil. As stated earlier, properties of the soil solution, adsorbate, and sorption sites will govern the types of chemisorption reactions that may take place. The solution speciation of cations/anions, as controlled by solution complexation reactions and the distribution of ion oxidation states will govern the saturation state of the soil solution with respect to potential precipitates. As one would anticipate, it is difficult to project what reactions may dominate solid-solution partitioning for ions without full knowledge of the solution chemistry and solid surface properties. For some ions, such as the alkali metals or halide anions, this task is simplified due to the predominance of a single oxidation state in natural systems and the high solubility of potential precipitate phases. However, this simplicity rapidly diminishes with departure from these bracketing groups within the periodic table of elements. Thus, the remaining discussion

will focus on illustrative examples of the types of chemical factors that influence chemisorption–precipitation versus an exhaustive review of the periodic properties of the elements. In order to illustrate the disparity in potential reaction paths for ions in soil solutions, the controls on solid-water partitioning for nickel (Ni) and selenium (Se) are reviewed in the following sections. These elements illustrate both the range of chemisorption–precipitation reactions that influence ion partitioning in soils and the degree of complexity inherent in monitoring and projecting these reactions in dynamic soil systems.

17.5.1 Nickel

Nickel is not commonly seen as a critical element in agricultural or environmental systems. However, as noted in a recent review by Hansch and Mendel (2009), it is considered to be an important micronutrient, and, for specific plant species, deficiencies in nickel availability may limit plant growth for agricultural (Bais et al., 2006) or phytoremediation applications (Wood et al., 2006). At higher concentrations in soil solutions, nickel may also exert a toxic effect on plant species (e.g., Khan et al., 2006). In ambient aqueous systems, nickel exists in the divalent oxidation state and is not subject to oxidation-state transformations under typical conditions. Nickel predominantly exists as a cationic species (Ni^{2+}) or various hydrolysis species (e.g., $NiOH^+$) at near-neutral pH (Baes and Mesmer, 1986). However, nickel may also form dissolved complexes in the presence of high concentrations of inorganic ions such as carbonate/bicarbonate and sulfate (Hummel and Curti, 2003; Chen et al., 2005) or organic ligands such as natural/synthetic carboxylic acids and dissolved humic compounds (Bryce and Clark, 1996; Baeyens et al., 2003; Strathmann and Myneni, 2004). It is anticipated that nickel may form complexes with dissolved sulfide under sulfate-reducing conditions, although the current state of knowledge is insufficient to ascertain the relative importance of these species in aqueous systems (Thoenen, 1999). The formation of solution complexes, especially with organic ligands (e.g., Strobel, 2001; Fröberg et al., 2006), may limit sorption of nickel to mineral surfaces in soils (see Section 17.5.1.2).

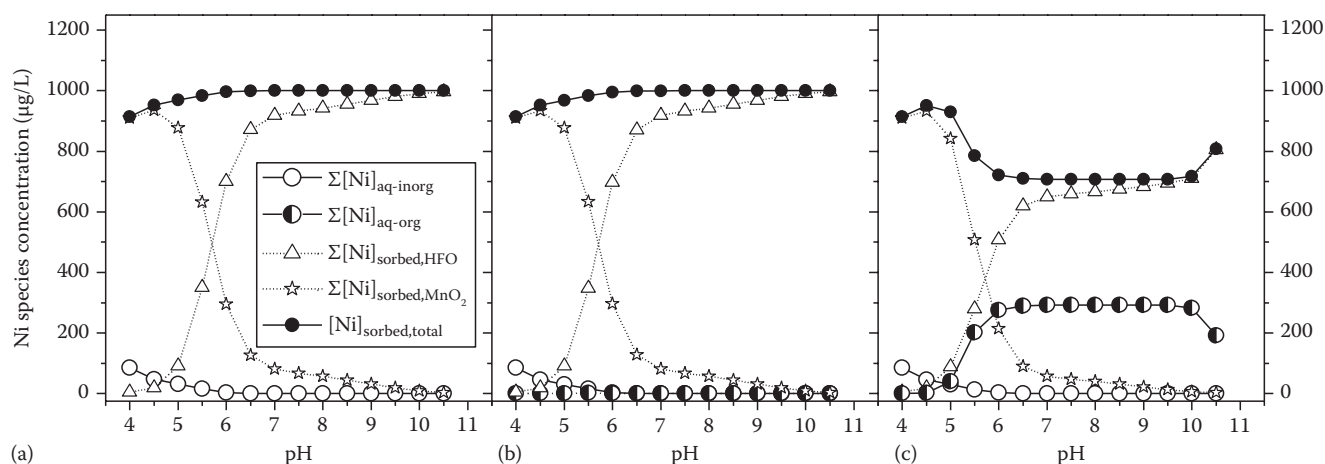
The solid-solution partitioning of Ni is chosen as a point of reference for ions that are not subject to a change in valence state due to shifts in redox characteristics in the soil solution. However, redox chemistry may exert an indirect control on Ni partitioning by governing the distribution of solid surfaces that may influence chemisorption reactions, as well as the distribution and concentrations of solution species that limit the solubility of Ni-bearing precipitates that may form. Nickel also provides an example of an ion that demonstrates a wide range of solid-solution partitioning behavior including adsorption, surface precipitation, and homogeneous precipitation.

17.5.1.1 Chemisorption

Nickel displays the commonly observed chemisorption behavior for cation adsorption onto soil minerals with uptake onto solid surface increasing with pH. Typically, the increase in

adsorption occurs over a narrow pH range, and the resultant plot of adsorption data has been given the name "adsorption edge" (e.g., Stumm, 1992; Sparks, 2003). Adsorption of nickel in soil environments is dependent on pH, temperature, and type of adsorbent (minerals or organic matter), as well as the concentration of aqueous complexing agents, competition from other adsorbing cations, and the ionic strength in the soil solution. Nickel has been shown to adsorb onto many solid components encountered in soils, including iron/manganese oxides, clay minerals (Dähn et al., 2003; Bradbury and Baeyens, 2005), and solid organic matter (Nachtegaal and Sparks, 2003). Sorption to iron/manganese oxides and clay minerals has been shown to be of particular importance for controlling nickel mobility in subsurface systems. The relative affinity of these individual minerals for nickel uptake will depend on the mass distribution of the adsorbent minerals as well as the predominant geochemical conditions (e.g., pH and Ni aqueous speciation). For example, the pH-dependent distribution of nickel between iron and manganese oxides (hydrous ferric oxide [HFO] and a birnessite-like mineral [nominally MnO_2]) for a representative soil solution composition is shown in Figure 17.3. Based on the available compilations for surface complexation constants onto these two solid phases (Dzombak and Morel, 1990; Tonkin et al., 2004), one would project the predominance of nickel sorption to MnO_2 at more acidic pH and the predominance of HFO (or ferrihydrite) at more basic pH. With increasing mass of MnO_2, the solid-phase speciation of nickel will be progressively dominated by sorption to this phase. There are examples of the relative preference of nickel sorption to manganese oxides over iron oxides for natural systems (e.g., Manceau et al., 2002; Kjoller et al., 2004; Manceau et al., 2007). As shown in Figure 17.3b, the presence of

humic/fulvic compounds along with simple organic acids may not significantly influence the extent of nickel sorption to oxide surfaces. This behavior is predicated on the availability of sorption sites at concentrations significantly greater than competing ligands in solution.

In contrast, the presence of ligands that form highly stable or multidentate solution complexes may exert greater influence on the degree of nickel sorption to oxide surfaces. As shown in Figure 17.3c, nickel sorption may be inhibited (or nickel desorption enhanced) through the formation of solution complexes with some classes of organic ligands such as hydroxamate siderophores (Dimkpa et al., 2008). Published stability constants are available for a commonly occurring hydroxamate siderophore, desferrioxamine B (DFB; Farkas et al., 1999). In order to model the nickel speciation in Figure 17.3c, equilibrium expressions for the protonation of DFB and its complexation with nickel were derived from published conditional stability constants (Evers et al., 1989; Farkas et al., 1999; see Table 17.2). As discussed previously, the production of siderophores provides a mechanism for plants/organisms to overcome the low solubility of metals such as nickel in soil systems where the abundance of solid sorption sites is high. As shown in Figure 17.3, the stability of solution complexes with carboxylic acids (natural or synthetic) and the relative availability of sites for chemisorption affect that degree of competition. For the hypothetical conditions modeled in Figure 17.3, only strong complexation with DFB significantly inhibits Ni adsorption to surface of hydrous Fe/Mn oxides. This behavior is similar to that observed in experimental systems for the synthetic chelating agent, EDTA (e.g., Bryce and Clark, 1996; Nowack et al., 1997). The model calculations presented in Figure 17.3 do not include the possible formation of ternary surface


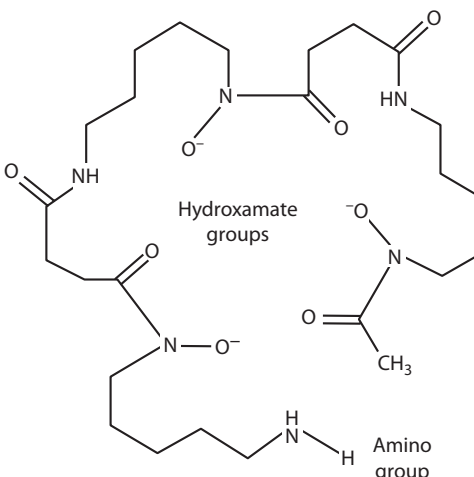


FIGURE 17.3 (a) Nickel sorption as a function of pH in the presence of a hypothetical soil with iron and manganese oxides reflective of the crustal abundance of these elements (Schulze, 2002; assumed 30% porosity with 185.0 g HFO L^{-1} and 1.66 g MnO_2 L^{-1}); no organic ligands. (b) Same conditions as in (a) but with 20 mg L^{-1} dissolved organic carbon (DOC; humics and fulvics) and 25 μM each of citrate, malonate, and oxalate. (c) Same conditions as in (a), but with 5 μM DFB added as the sole organic ligand. Nominal water composition: 0.005 mol L^{-1} NaCl, 0.001 mol L^{-1} K_2SO_4, 0.001 mol L^{-1} $MgNO_3$, 0.001 mol L^{-1} $CaCO_3$, and 17 μM Ni (1 mg Ni L^{-1}). Model predictions using Visual MINTEQ (2009) Version 2.61 with available surface complexation parameters derived from Dzombak and Morel (1990) and Tonkin et al. (2004), and metal-DOC speciation using default settings in the DOC (SHM) module (Gustafsson, 2001); kaolinite set as an "infinite" solid for pH titration. This model does not make use of the alternate hypothetical reference states proposed by Kulik (2002a, 2002b) or Sverjensky (2003).

TABLE 17.2 Complexation Reactions between Ni(II) and DFB, a Microbially Produced Trihydroxamate Siderophore in the Soil Rhizosphere

Acid–Base Reactions		
Stoichiometry	Log K (25°C)	Structure of DFB
$H_3DFB + H^+ = H_4DFB^+$	8.32	
$H_3DFB - H^+ = H_2DFB^-$	−8.74	
$H_3DFB - 2H^+ = HDFB^{2-}$	−17.84	
$H_3DFB - 3H^+ = DFB^{3-}$	−27.95	
Complexation Reactions		
$Ni^{2+} + H_3DFB - 3H^+ = NiDFB^-$	−20.41	
$Ni^{2+} + H_3DFB - 2H^+ = NiHDFB$	−0.95	
$Ni^{2+} + H_3DFB - H^+ = NiH_2DFB^+$	−1.89	
$Ni^{2+} + H_3DFB = NiH_3DFB^{2+}$	3.90	

Equilibrium reaction expressions and associated constants for protonation and complexation with nickel were derived from Evers et al. (1989) and Farkas et al. (1999), respectively. All constants have been recalculated to zero ionic strength using the Davies equation for the estimation of single-ion activities (Stumm and Morgan, 1981, p. 135). Reaction expressions from the referenced sources were converted to the reaction format required within the Visual MINTEQ (2009) database using H^+, Ni^{2+}, and H_3DFB as components (MINTEQA2/PRODEFA2, 1999).

complexes with DFB or other multidentate ligands that might serve as a bridging ligand between Ni and an oxyhydroxide surface (e.g., Nowack and Sigg, 1996; Nowack, 2002).

As previously noted, adsorption of nickel onto mineral surfaces may serve as a precursory step to the formation of trace precipitates that reduce the potential for desorption with changes in soil solution chemistry. This may be realized through the nucleation and growth of surface precipitates on clay mineral surfaces due to continued uptake of nickel. Three categories of surface precipitation have been identified in experimental systems: (1) heterogeneous nucleation of pure Ni-bearing phases such as hydroxides (e.g., Scheinost et al., 1999), (2) coherent growth of Ni-bearing solid phases that mimic the structure of the adsorbent (e.g., Dähn et al., 2002), and (3) nucleation of mixed-metal precipitates within the solid–water interface (e.g., Scheckel and Sparks, 2000, 2001; Scheckel et al., 2000; Dähn et al., 2006). This type of process may compete with other adsorption processes, such as ion exchange, depending on the prevailing soil solution chemistry and characteristics of the clay mineral (e.g., Elzinga and Sparks, 2001).

17.5.1.2 Precipitation

Nickel may be immobilized within soils through formation of pure nickel precipitates such as hydroxides, silicates, or sulfides (Merlen et al., 1995; Mattigod et al., 1997; Scheidegger et al., 1998; Thoenen, 1999; Scheinost and Sparks, 2000; Peltier et al., 2006) or through coprecipitation with other soil-forming minerals such as silicates, iron oxides/sulfides, or carbonates (Manceau et al., 1985; Manceau and Calas, 1986; Huerta-Diaz

and Morse, 1992; Ford et al., 1999a; Hoffmann and Stipp, 2001). Predicted nickel concentrations in the presence of sulfide for several potential pure nickel precipitates are shown in Figure 17.4a. These data suggest that phyllosilicate and LDH precipitates (incorporating aluminum) may limit Ni solubility in soils. These data also point to the limited capability of pure nickel carbonates and hydroxides in controlling dissolved nickel concentrations to sufficiently low values except under very alkaline conditions. For LDH precipitates, calorimetric measurements have demonstrated that the interlayer anion exerts significant influence on the precipitate stability (Peltier et al., 2006). In the presence of dissolved sulfide, the precipitation of a nickel sulfide may plausibly control the concentration of dissolved nickel. The influence of dissolved silicate on the stability of Ni-bearing precipitates is shown in Figure 17.4b. According to these data, nickel-bearing phyllosilicate and/or LDH precipitates possess large stability fields indicating their relative importance to controlling nickel solubility under a range of conditions. These calculations point to the importance of dissolved aluminum and silicon concentrations in the soil solution relative to the potential sequestration of nickel via precipitation (Ford et al., 1999b; Scheinost et al., 1999). As discussed in Section 17.5.1.1, the formation of these nickel-bearing precipitates may be facilitated through initial adsorption onto clay minerals within the soil.

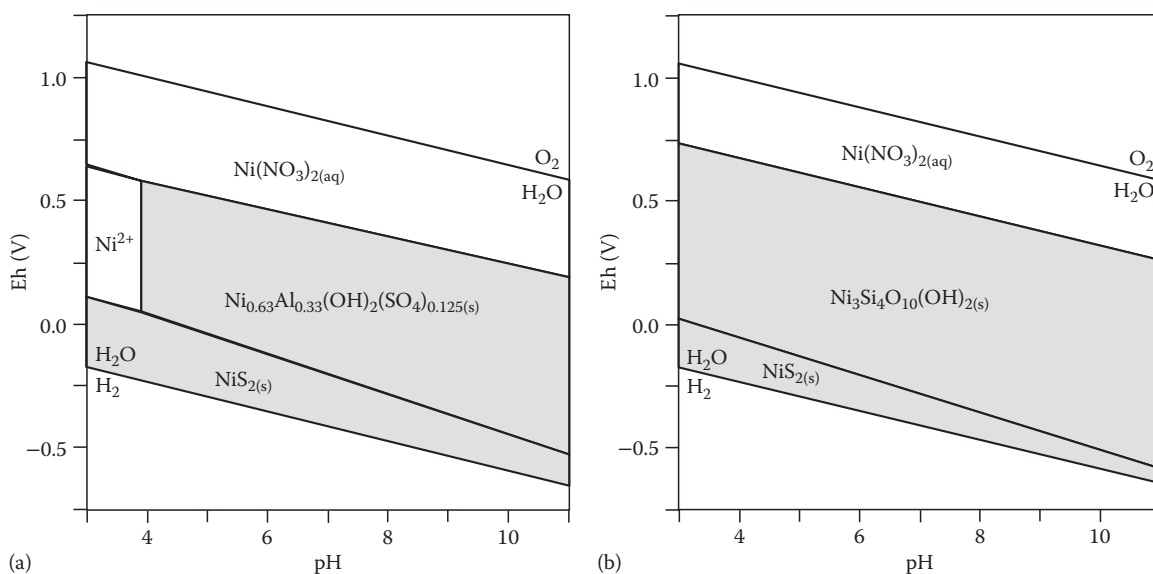
Attenuation of nickel may also occur via coprecipitation during the formation of (hydr)oxides or sulfides of iron. These minerals have been observed to form at the boundaries between oxidizing and reducing zones within soil systems. There are numerous laboratory and field observations that demonstrate


FIGURE 17.4 Eh–pH diagrams for nickel at 25°C. (a) System Ni–H_2O–Ca–Al–NO_3–HCO_3–SO_4 (2 mg Ni L^{-1}; 40 mg Ca L^{-1}; 3 mg Al L^{-1}; 6 mg NO_3 L^{-1}; 60 mg HCO_3 L^{-1}; 100 mg SO_4 L^{-1}). Stability fields for solids are shaded gray (Vaesite = NiS_2). (b) Same system plus 3 mg Si L^{-1}. Thermodynamic data for $Ni_3Si_4O_{10}(OH)_2$ and $Ni_{0.63}Al_{0.33}(OH)_2(SO_4)_{0.125}$ are from Peltier et al. (2006). (Note that the solubility of the Ni–Al–SO_4 LDH was adjusted to correct for charge imbalance for the chemical structure published in Peltier et al. [2006].)

the capacity of these precipitates for nickel uptake (Schultz et al., 1987; Huerta-Diaz and Morse, 1992; Coughlin and Stone, 1995; Ford et al., 1997, 1999a). Under these circumstances, the solubility of nickel will depend on the stability of the host precipitate phase. For example, iron oxide precipitates may alternatively transform to more stable forms (Ford et al., 1997), stabilizing coprecipitated nickel over the long term, or these precipitates may dissolve concurrently with changes in soil solution redox chemistry (e.g., Zachara et al., 2001).

17.5.2 Selenium

Selenium provides an example of an element that is subject to significant changes in solution and solid speciation as influenced by changes in system redox. Selenium is a metalloid exhibiting physical and chemical properties between that of metals and nonmetals. It chemically resembles sulfur and exists in organic and inorganic chemical forms. Inorganic species include selenide [Se(–II)], elemental selenium [Se(0)], selenite [Se(IV)], and selenate [Se(VI)] (e.g., Fernandez-Martınez and Charlet, 2009). Organic species include methylated compounds, selenoamino acids, and selenoproteins and their derivatives. The speciation of selenium is greatly influenced by the pH and redox conditions of the environment (Figure 17.5). For example, Se(–II) exists in a reducing environment as hydrogen selenide (H_2Se) and as metal selenides. Reduction of selenate to selenite and Se(0) has been shown to decrease its mobility in saline, mildly alkaline water (White et al., 1991). When dissolved in water, H_2Se can oxidize to elemental selenium. Elemental selenium is stable in a reduced environment, but it can be oxidized to selenite and to selenate by a variety of microorganisms (Sarathchandra and Watkinson, 1981; Dowdle and Oremland, 1998).
FIGURE 17.5 Eh–pH diagram for selenium at 25°C using thermodynamic data from Seby et al. (2001). $\Sigma Se = 10^{-5}$ M (790 μg L^{-1}). Solid stability field for elemental selenium is shaded gray.

Various strains of bacteria have been identified to facilitate selenate reduction in soil systems. Two microbial processes, namely, methylation of selenium and reduction of both selenate and selenite to Se(0), have a major influence on the fate and mobility of this element in the environment (Dungan and Frankenberger, 1999; Dungan et al., 2003). Methylation of selenium, and subsequent selenium volatilization, leads to dissipation of soil selenium to the atmosphere. Environmental factors such as the existing microbial community, pH,

temperature, moisture, and organic amendments control the rate of selenium volatilization from seleniferous soils (Frankenberger and Karlson, 1989; Zhang and Frankenburger, 1999). Under flooding conditions, part of the methylated selenium may be transported in water, thus decreasing selenium volatilization to the atmosphere (Zhang and Frankenburger, 1999). The addition of organic amendments to soils has been reported to stimulate indigenous microbes to methylate selenium (Abu-Erreish et al., 1968; Frankenberger and Karlson, 1989); whereas, organic substrates added to ponded sediments (submerged soils) have been found to accelerate the reduction of selenate and selenite to Se(0) (Tokunaga et al., 1996) and similar effects were reported in laboratory batch experiments (Zhang et al., 2003).

Mechanisms for selenium reduction by microbes are complex as it occurs under both aerobic (Lortie et al., 1992) and anaerobic conditions (Oremland et al., 1989, 1990; Tomei et al., 1992). Both dissimilatory and detoxification mechanisms are possible (Oremland, 1994). The occurrence of sequential reduction of selenate to selenite and then to Se(0) is suggested after amendment of contaminated soils with barley straw under field capacity moisture conditions (Camps Arbestain, 1998). The rate of selenate to selenite reduction in wastewaters is proportional to their respective concentrations in solution and also to the amount of the microbial biomass (Rege et al., 1999). A recent study has documented the occurrence of both intracellular and extracellular Se(0) granules in three phylogenetically and physiologically distinct bacteria that are able to respire selenium oxyanions, suggesting that this phenomenon appears to be widespread among such bacteria (Oremland et al., 2004). The metal sites of selenate reductase from *Thauera selenatis* have been characterized (Maher et al., 2004); the enzyme was found to contain Se in a reduced form (probably organic) and the Se is coordinated to both a metal (probably Fe) and carbon. Assessment of Se(IV) and Se(0) reduction in anaerobic microcosms demonstrated the sequential formation of Se(0) and ultimately Se(–II) during incubation with elemental selenium and/or lactate as electron donors for microbial reduction (Herbel et al., 2003). Dissolved Se(–II) did not accumulate in pore water during incubation due to precipitation with ferrous iron to form FeSe(s), which was determined via solid-phase characterization using x-ray absorption spectroscopy.

17.5.2.1 Chemisorption

As noted above, the most common species of selenium in soil solution are in the form of oxyanions. Thus, selenium adsorption onto soil minerals tends to be greatest under acidic pH with a gradual decrease as pH increases. In contrast to cation adsorption, the decrease in anion adsorption with increasing pH is more gradual, and the resultant plot of these adsorption data has been given the name "adsorption envelope" (e.g., Stumm, 1992; Sparks, 2003). Selenate and selenite adsorption behavior on individual soil minerals (Fe, Al, and Mn oxides, kaolinite, and calcite) and whole soils throughout the United States has been documented (Neal et al., 1987; Neal and Sposito, 1989; Zachara et al., 1994). This research demonstrated the importance of Fe- and Al-oxide surfaces for selenium adsorption onto soils and highlighted the dependence of the extent of adsorption on the pH of soil solution and the presence of anions that compete for adsorption sites. Additional review of the published literature is provided in the following.

Selenate has been shown to behave like sulfate with minimal adsorption and high mobility (Goldberg and Glaubig, 1988; Neal and Sposito, 1989); whereas, selenite behaves analogously to phosphate, with greater adsorption than selenate (Neal et al., 1987; Barrow and Whelan, 1989a; Zhang and Sparks, 1990). Strawn et al. (2002) have observed selenite and selenate associated with iron-bearing minerals in acid-sulfate soils. In these soils, selenite was predominantly associated with iron oxyhydroxides and selenate was associated with jarosite, presumably in a coprecipitated form. Adsorption of selenite on goethite decreases with increasing pH, with decreasing selenite concentration, and with competing anions such as phosphate, silicate, citrate, molybdate, carbonate, oxalate, and fluoride (Balistrieri and Chao, 1987). More selenite is adsorbed onto montmorillonite than on kaolinite (Frost and Griffin, 1977). Selenite adsorption in seleniferous soils is decreased in the presence of sulfate, nitrate, and phosphate (Pareek et al., 2000). Selenite adsorption by aluminum hydroxides is adversely affected by organic acids (Dynes and Huang, 1997). Desorption of selenate is faster and more nearly complete than selenite after adsorption and incubation in soil (Barrow and Whelan, 1989b). Differences in the stability of selenate and selenite chemisorption to ferrihydrite are illustrated in Figure 17.6. Selenite adsorption predominates for most of the modeled pH range, but there is a small stability field for selenate adsorption in the pH range 7 < pH < 9, in part, due to the pH-dependent distribution of selenium oxyanion oxidation state. As shown, model predictions indicate limited competition from competing oxyanions common to soil solutions (e.g., carbonate, silicate, and sulfate) when available surface-site densities are far from saturation.

Selenite selectively adsorbs at the carbonate (CO_3^{2-}) site on calcite ($CaCO_3$) via ionic exchange, forming a two-dimensional solid solution of the form $Ca(SeO_3)_x(CO_3)_{1-x}$ at the interface; under identical chemical conditions, selenate adsorption is inhibited (Cheng et al., 1997). An earlier study showed selenate substitution in calcite may also be supported under appropriate conditions (Reeder et al., 1994).

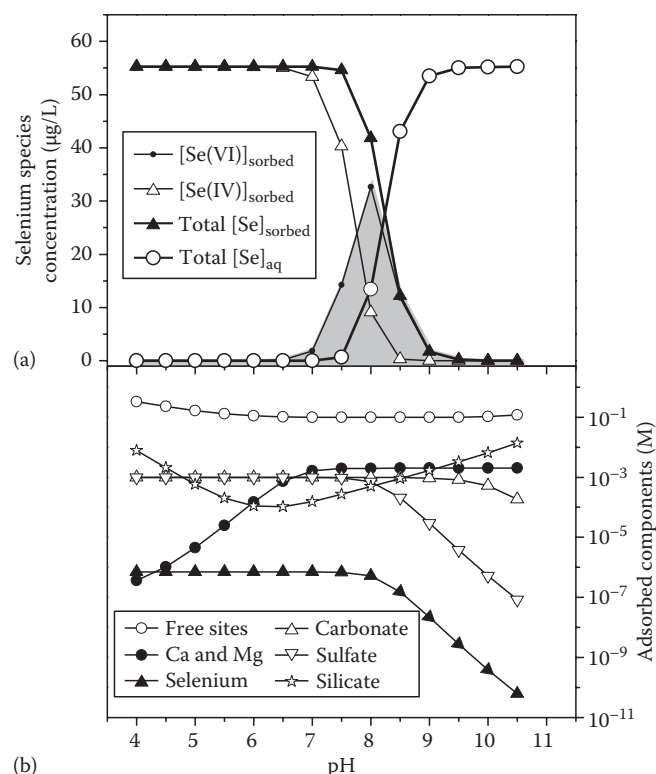
Mechanisms of selenium adsorption have been studied from both macroscale batch and microscale spectroscopic approaches. The presence of either selenate or selenite lowers the electrophoretic mobility and decreases the PZC of ferrihydrite and goethite, suggesting inner-sphere complexation for both selenate and selenite species (Su and Suarez, 2000). Both in situ attenuated total reflectance–Fourier transform infrared (ATR–FTIR) and diffuse reflectance infrared Fourier transform (DRIFT) spectra indicated formation of bidentate complexes of selenate with ferrihydrite, and the DRIFT spectra of selenite on goethite indicated formation of bridging bidentate complex of selenite.


FIGURE 17.6 (a) Selenium species adsorption as a function of pH in the presence of a hypothetical soil with iron oxide content reflective of the crustal abundance (Schulze, 2002; assumed 30% porosity with 185.0 g HFO L⁻¹). (b) Total component adsorption for modeled water composition. Nominal water composition: 0.005 M NaCl, 0.001 M K₂SO₄, 0.001 M MgNO₃, 0.001 M CaCO₃, and 0.7 μM Se (55.2 μg Se L⁻¹). Model predictions using Visual MINTEQ (2009) Version 2.61 with available surface complexation parameters derived from Dzombak and Morel (1990) at a fixed Eh = 500 mV; kaolinite set as an "infinite" solid for pH titration. This model does not make use of the alternate hypothetical reference states proposed by Kulik (2002a, 2002b) or Sverjensky (2003).

These results are consistent with an earlier in situ extended x-ray absorption fine structure (EXAFS) spectroscopic study (Manceau and Charlet, 1994) that shows that selenate forms an inner-sphere binuclear bridging surface complex on hydrous ferric oxide and goethite. On the contrary, an earlier EXAFS study (Hayes et al., 1987) concluded that selenate forms an outer-sphere surface complex on goethite. A recent combined data set of Raman and ATR–FTIR spectra indicate that both inner- and outer-sphere surface complexes of selenate occur on goethite, as predominantly monodentate inner-sphere surface complexes at pH < 6, and as predominantly outer-sphere surface complexes at pH > 6 (Wijnja and Schulthess, 2000).

17.5.2.2 Precipitation

Selenium has the potential of forming precipitates for all of its oxidation states (Seby et al., 2001; see Figure 17.7). For selenate and selenite, this includes precipitates with common major cations in soil solutions (Ca, Mg) as well as transition metals (Fe, Mn) or heavy metals that may be anticipated in contaminated
FIGURE 17.7 Eh–pH diagram for selenium at 25°C using thermodynamic data from Seby et al. (2001). System Se–H₂O–Fe–Ca, with ΣSe = 10⁻⁵ M (790 μg L⁻¹), ΣFe = 10⁻⁴ M (5.6 mg L⁻¹), and ΣCa = 10⁻² M (400 mg L⁻¹). Solid stability fields for elemental selenium, hydrous calcium selenite, and ferrous selenide are shaded gray. FeSe₂ was suppressed (data not available in the Seby et al., 2001); however, the stability field of the diselenide would be intermediate between elemental selenium and FeSe.

soils (Rai et al., 1995; Sharmasarkar et al., 1996). These phases are anticipated to primarily be significant in situations where selenium concentrations are highly elevated. Reduction to form elemental selenium [Se(0)] can result in very low concentrations of dissolved selenium. In general, it has been observed that selenium reduction to insoluble Se(0) results in immobilization and stabilization of this element in the soil matrix, since the reoxidation reaction of Se(0) to soluble selenate and selenite is relatively slow (Tokunaga et al., 1994; Zawislanski and Zavarin, 1996; Dowdle and Oremland, 1998; Losi and Frankenberger, 1998). Abiotic reduction of selenite to Se(0) was also suggested in SRB biofilms (Hockin and Gadd, 2003). Further reduction to selenide [Se(–II)] can lead to precipitation of metal selenides, including ferrous iron and manganese selenides, similar to the formation of metal sulfides under sulfate-reducing conditions. As demonstrated by Scheinost and Charlet (2008a) and Scheinost et al. (2008b), selenite may be reduced and precipitated via abiotic reactions with Fe(II)-bearing minerals in soils. The propensity to form elemental selenium versus ferrous-selenide precipitates will likely be governed by pH, major ion composition of the soil solution, and the solubility of ferrous iron.

While not commonly observed, it is anticipated that many suboxic soil environments (e.g., redoximorphic soils) contain green rust, which is a mixed ferrous, ferric hydroxide that also contains interlayer anions such as sulfate and carbonate in its structure (Feder et al., 2005). Identification of green rusts in soils

is hampered by the rapid oxidation of green rusts by atmosphere oxygen, and for this reason, they have not been commonly reported. However, recent thermodynamic and spectroscopic studies give direct evidence for the existence of green rusts in soils (Hansen et al., 1994; Trolard et al., 1997, 2007; Feder et al., 2005). Due to high reactivity, green rust minerals are envisioned as potential reducing agents of a number of anions such as nitrate, chromate, and selenate (Johnson and Bullen, 2003). Direct evidence for the formation of reduced selenium species under anoxic conditions via abiotic redox reactions with sulfate green rust was provided using x-ray absorption near-edge spectroscopy (XANES) and Fourier transform EXAFS spectroscopy (Myneni et al., 1997). The mechanism of selenate reduction was described by the following equation:

$$HSeO_4^- + 4Fe^{(II)}_4Fe^{(III)}_2(OH)_{12}SO_4 \cdot 3H_2O$$

$$\rightarrow HSe^- + 8Fe_3O_4 + 4SO_4^{2-} + 8H^+ + 32H_2O \qquad (17.1)$$
in which sulfate green rust was oxidized to form magnetite, whereas selenate was reduced to Se(0) and subsequently to selenide. In addition, a laboratory study has demonstrated that a significant fraction of dissolved selenate can be coprecipitated with Fe(II) and Fe(III) ions to form Fe(II)–Fe(III) hydroxyselenate green rust with simultaneous reduction of an equal amount of selenate anions to selenite anions (Refait et al., 2000; similar to partitioning to LDH phases, You et al., 2001). In the subsurface environment, selenate reduction by coprecipitation and adsorption pathways can occur when reducing conditions develop (Pickering et al., 1995). In the coprecipitation–reduction pathway, reductive dissolution of Fe(III) oxides precipitates green rust with selenate followed by selenate reduction to Se(0) and selenide. Reduction of selenium oxyanions to Se(0) has also been observed in the presence of iron sulfides (Bruggeman et al., 2005) and ferrous hydroxide (Zingaro et al., 1997).

In summary, the chemical behavior of nickel and selenium point to the importance of identifying aqueous and solid speciation in confirming the processes controlling element partitioning for a given soil system. Chemical equilibrium models provide a tool for assessing potential endpoints for these partitioning reactions, but the accuracy of these projections will depend on the adequacy of the supporting thermochemical database for relevant solution and solid species. Advances have been made in modeling chemisorption and precipitation reactions, in part, due to developments in analytical approaches to identify aqueous and solid speciation for trace elements in soils. For trace-element partitioning, it is increasingly understood that the initial form of the chemisorbed solute may represent a metastable state relative to its long-term mobility. Due to the internal influence of biotic respiration in concert with external fluxes of aqueous and gaseous components physically transported through the soil matrix, the composition of the soil solution and associated solids will change in time. Ultimately, knowledge of the rates and extents of these aqueous and mineralogic changes will prove critical for understanding the dynamics of solute partitioning for soil systems.

18.1 Introduction

Abiotic catalysis plays a vital role in many physicochemical processes in soil and related environments. Clay minerals, metal (oxy)hydroxides and oxides, and dissolved metals often demonstrate their ability to catalyze the transformations of natural organic and anthropogenic organic compounds, metals, metalloids, and other inorganics.

Metal (oxy)hydroxides and oxides and clay minerals have the ability to catalyze the transformation of biomolecules and the resultant formation of humic substances (Huang and Hardie, 2009). Iron (oxy)hydroxides and oxides (Scheffer et al., 1959; Shindo and Huang, 1984a; Wang and Huang, 2000a, 2000b; Gonzalez and Laird, 2004) and especially Mn oxides (Shindo and Huang, 1982, 1984a, 1984b; Kung and McBride, 1988; Wang and Huang, 1992, 2000a,b; Jokic et al., 2001a, 2001b, 2004a, 2004b; Hardie et al., 2007) are most reactive in mediating the transformations of phenolic compounds, amino acids, and sugars. Other organic compounds such as aromatic amines and organic acids can also be oxidatively transformed by abiotic

catalysis (Furukawa and Brindley, 1973; McBride, 1979; Jauregui and Reisenauer, 1982; Stone and Morgan, 1984b).

Abiotic catalytic reactions are also important in the transformations of anthropogenic organic compounds such as pesticides, antibiotics, explosives, and dyes (Theng, 1974, 1979; Cheng, 1991; Stone and Torrents, 1995; Smolen and Stone, 1998; Wang and Arnold, 2003; Szecsody et al., 2004; Barrett and McBride, 2005; Baldrian et al., 2006; Hofstetter et al., 2006; Kang et al., 2006; Rubert and Pedersen, 2006; Fimmen et al., 2007; Cheng et al., 2008; Zhang et al., 2008). Soils and sediments contain a series of solid surfaces and dissolved constituents. These components can catalyze the transformation reactions through Brønsted and Lewis acidity, hydrolysis, and oxidative or reductive processes, which can result in the alteration of transformation pathways and kinetics, thereby influencing the toxicity and environmental fate of these organic compounds.

Manganese oxides and Fe-bearing minerals have the ability to catalyze the transformations of metals, metalloids, and/or other inorganics. Manganese oxides are effective catalysts in promoting many reactions such as the transformation of As(III)

to As(V) (Oscarson et al., 1981a; Chiu and Hering, 2000; Power et al., 2005; Feng et al., 2006b), Fe(II) to Fe(III) (Krishnamurti and Huang, 1987, 1988), Pu(III/IV) (Cleveland, 1970; Amacher and Baker, 1982; Morgenstern and Choppin, 2002) and Pu(V) (Keeneykennicutt and Morse, 1985; Duff et al., 1999) to Pu(VI), as well as Cr(III) to the more toxic and mobile Cr(VI) (Bartlett and James, 1979; Amacher and Baker, 1982; Stepniewska et al., 2004; Negra et al., 2005; Feng et al., 2007). Manganese(IV) oxides also catalyze the oxidation of nitrite to nitrate (Bartlett, 1981; Luther and Popp, 2002), and NH_3 and organic N to N_2 (Luther et al., 1997). Heterogeneous oxidation/reduction reactions involving electron transfer between metals/metalloids and Fe-bearing minerals have been demonstrated (Wehrli and Stumm, 1989; Ilton and Veblen, 1994; Peterson et al., 1996; White and Peterson, 1996; Myneni et al., 1997; Powell et al., 2004; Jeon et al., 2005; Jung et al., 2007; Jang and Dempsey, 2008; Scheinost and Charlet, 2008; Su and Puls, 2008). Further, it has been suggested that reduced Fe and Mn minerals are responsible for catalyzing nitrate immobilization into dissolved and humic N fractions in soils and sediments (Davidson et al., 2003; Huygens et al., 2008).

Therefore, abiotic catalysis plays an important role in the transformation of organics, metals, metalloids, and other inorganics in soil and related environments. The impact of abiotic catalysis on environmental quality and ecosystem integrity deserves increasing attention.

18.2 Fundamentals of Catalysis

18.2.1 Definition of Catalysis

The process of changing the rate of a chemical reaction by the use of a catalyst is termed catalysis, coined by Berzelius in 1836 to describe some enhanced chemical reactions (Williams, 1965). The accepted definition of a catalyst, due to Oswald, is that it is a substance that changes the speed of a chemical reaction without itself undergoing any permanent chemical change. Since a reactant or a product may also be a catalyst, Bell (1941) suggests the definition, "A catalyst is a substance which appears in the rate expression to a power higher than that to which it appears in the stoichiometric equation." Actually many substances classified as catalysts are destroyed either as a result of the process that gives them their catalytic activity or because of subsequent combination with the products (Moore and Pearson, 1981). From a practical point of view, a catalyst is a substance that changes the rate of a desired reaction, regardless of the fate of the catalyst itself.

An important criterion of a catalyst is that it changes the mechanism of the parent reaction (Moore and Pearson, 1981). Without this change in mechanism, the observed change in rate could not occur. Since catalysts increase the rate of reaction, the mechanism must change to one that is easier for the system to follow, involving, in general, a lower energy barrier. Therefore, the catalyst provides an alternative pathway by which the reaction comes to equilibrium, although it does not alter the position of the equilibrium (Daintith, 1990). The catalyst itself takes part

in the reaction. In certain circumstances, very small quantities of catalyst can speed up very large reactions. Some catalysts are also highly specific in the type of reaction they catalyze, particularly in biochemical reactions.

18.2.2 Homogeneous and Heterogeneous Catalysis

The process of changing the rate of a chemical reaction by the use of a catalyst that has the same phase as the reactant is homogeneous catalysis (e.g., dissolved metals in catalyzing organic reactions or enzymes in biochemical reactions) (Daintith, 1990). A process driven by a catalyst that has a phase different from the reactant is heterogeneous catalysis (e.g., metal oxides in catalyzing organic and inorganic reactions). In heterogeneous catalysis, the catalyzed reaction steps take place at or very close to the solid surface. These steps may be between molecules adsorbed on the catalyst surface or may involve the topmost atomic layers of the catalysts (Twigg, 1989). The sequence of stages for a heterogeneous catalytic reaction is shown in Table 18.1. Any of these stages, if slow, may limit the overall rate of a catalytic reaction. Distinctions are often drawn between catalysts that are film-diffusion controlled (i.e., limited by stages 1 and/or 7), pore-diffusion controlled (i.e., limited by stages 2 and/or 6), and reaction controlled (i.e., limited by stages 3, 4, and/or 5). There is a complex interaction between the relative importance of these different stages and the resulting catalytic effect on organic and inorganic reactions.

Advances in surface science and catalysis are presented in a treatise edited by Hightower et al. (1996). Both homogeneous and heterogeneous catalytic reactions are significant in soil and environmental sciences (Bartlett, 1986; Huang, 1990, 1991b; Stumm, 1992; Stone and Torrents, 1995; Smolen and Stone, 1998; Davidson et al., 2003; Livens et al., 2004; Stepniewska et al., 2004; Barrett and McBride, 2005; Hofstetter et al., 2006; Cheng et al., 2008; Scheinost and Charlet, 2008; Zhang et al., 2008).

TABLE 18.1 Sequence of Stages in the Catalysis of a Reaction by a Heterogeneous Catalyst[a]

1. Transport of reactants through the liquid or gas phase to the exterior of the catalyst
2. Transport of reactants through the pore system of the catalyst to a catalytically active site
3. Adsorption of reactants at the catalytically active site
4. Chemical reactions between reactants at the catalytically active site (frequently several steps)
5. Desorption of products from the catalytically active site
6. Transport of products through the catalyst pore system from the catalytically active site to the exterior of the catalyst
7. Transport of products into the liquid or gas phase from the exterior of the catalyst

[a] Several different catalytically active sites may be involved. Adsorption, possibly followed by reaction, may occur at one site, followed by transport of an intermediate product to a different site for further reactions.

18.2.3 Proton and Electron Transfer Catalysis

Brønsted acid–base catalysis is effective because proton transfers are generally rapid compared with the making and breaking of other chemical bonds. Therefore, reactions involving proton transfer in a typical acid or base catalysis are rapid compared with similar reactions of comparable free energy. The rate of a chemical reaction is related to the steric hindrance involved. Steric hindrance, which is the repulsion of nonbonded atoms in an activated complex, is the most important factor in determining the activation energy of a reaction (Moore and Pearson, 1981). Since a proton lacks the filled inner electron shells usually responsible for repulsion and is not surrounded by other groups, it is quite free from steric hindrance effects. Proton transfers involving oxygen–hydrogen bonds are generally rapid but they are not instantaneous. For instance, in the ionization of water, the activation energy is at least 57 kJ mol^{-1} (the heat of the reverse reaction) and the entropy of activation is negative; therefore, the rate constant (5×10^{-7} mol L^{-1} s^{-1}) is small (Moore and Pearson, 1981). This example demonstrates that an unfavorable equilibrium constant must necessarily make a reaction slow, even if other factors are quite favorable. Given a favorable equilibrium, proton transfers involving O and N bonds to H are almost always very fast, approaching diffusion control in many cases. Exceptions can occur if the proton is in a well-shielded position (Kresge, 1975).

Catalysis by proton transfer is by far the most common in homogeneous reactions. For those reactions that are subject to proton transfer catalysis, an expected relationship exists between the strength of the acid or base, as determined by its ionization constant, and its efficiency as a catalyst, determined by the observed rate constant. This relationship is best shown by the Brønsted catalysis law (Brønsted, 1928):

$$k_a = C_A K_a^\alpha \quad k_b = C_B K_b^\beta, \tag{18.1}$$

where
  - k_a and k_b are the rate constants (also termed the catalytic constants) for acid and base catalytic reactions, respectively
  - K_a and K_b are the acid and base ionization constants
  - C_A, C_B, α, and β are constants characteristic of the reaction, the solvent, and the temperature

Normally, α and β are positive and have values between 0 and 1. In the Brønsted equation, a low value of α and β signifies a low sensitivity of the catalytic constant to the strength of the catalyzing acid or base, and vice versa. Proton transfer catalysis is of significance in soils and associated environments (Theng, 1974, 1979; Cheng, 1991; Nannipieri and Gianfreda, 1998) as discussed later.

In acid catalysis of reactions involving negatively charged organic molecules, adsorption of a proton reduces their negative charge and, thus, facilitates the transfer of electrons (Steinberger and Westheimer, 1949, 1951). In agreement with this explanation, a number of multiply charged cations act as catalysts in the transformation of organic compounds (Stone and Torrents, 1995).

Presumably a metal-organic complex is formed that reduces the negative charge and increases the electron transfer. The catalytic efficiency of a metal ion depends both on its positive charge and on its ability to form a stable complex and chelate the reactant. In such reactions, the metal ions are acting as generalized acids. However, metal ions have some significant advantages over protons. They can have greater charges, which lead to greater polarization of the reactant molecules. Unlike the proton, metal ions can be stabilized by other ligands and, thus, can exist in neutral or even basic solutions. The high coordination numbers of metal ions permit the binding of a substrate at more than one site. This advantage helps to make metal ions very efficient catalysts for the hydrolysis of many organic compounds (Kroll, 1952). Further, some metal ions have the ability to simultaneously bind both a substrate and a reagent. This can have the effect of a template, in which the two reactants are assembled (brought into close proximity) prior to combination (Basolo and Pearson, 1968).

Many metal ions, especially of the transition series, have several stable oxidation states, which enables them to act as catalysts in certain redox reactions. Transition metals are the best catalysts, in most cases, for catalyzing reactions that are slow for symmetry reasons (Pearson, 1976). In addition to the slow three-body reactions, a second class of slow reactions is forbidden by orbital symmetry (Moore and Pearson, 1981). Even when the reaction is thermodynamically favorable, a large energy barrier can exist. Such reactions are prime candidates for catalysis. The reason why transition metals are often the best catalysts is due to their partly filled d orbitals, which have symmetry properties that are different from those of s and p orbitals. Because of the special properties of metal ions, particularly transition metal ions, they can catalyze a wide variety of organic and inorganic reactions in soil and related ecosystems.

18.3 Abiotic Catalysis of Natural and Anthropogenic Organic Compounds

18.3.1 Oxidative Transformation of Phenolic and Other Organic Compounds

18.3.1.1 Phenolics

Phenolics are the most widely distributed class of plant secondary metabolites and play an important role in regulating nutrient cycling in the terrestrial environment (Hättenschwiler and Vitousek, 2000). Phenolics may be released from natural sources, industrial activities, or agricultural practices; and they can harm the environment, especially in the form of pesticides (e.g., chlorophenols), nitrophenols, hormones, and azo dyes (Gianfreda et al., 2006). The oxidative transformation of phenolics can be accelerated enzymatically and nonenzymatically (Huang, 1990; Bollag et al., 1995; Naidja et al., 2000; Gianfreda et al., 2006). Soil minerals, in particular (SRO) Fe(III) and Mn(IV) oxides, play an important role in catalyzing the abiotic oxidative polymerization of phenolic compounds and the subsequent formation of humic

substances (Wang et al., 1986; Pal et al., 1994; Bollag et al., 1998; Huang, 2004; Huang et al., 2005). The surfaces of soil mineral colloids promote oxidative polymerization reactions by acting as electron acceptors. The rate-determining step in the formation of humic acids (HAs) from polyphenols is apparently the formation of a semiquinone-free radical involving a single electron transfer reaction (Schnitzer, 1982). Semiquinones couple with each other to form a stable HA polymer. The coupling of free radicals requires little activation energy, in contrast to electron transfer reactions (Chang and Allen, 1971). Therefore, coupling of semiquinones rather than the formation of quinones should be kinetically the preferred reaction pathway in the transformation of polyphenols to humic macromolecules.

Manganese(IV) oxides, such as birnessite (δ-MnO_2), cryptomelane (α-MnO_2), and pyrolusite (β-MnO_2), which commonly occur in soils and sediments (McKenzie, 1989), are powerful catalysts of the abiotic oxidation of polyphenols, such as catechol (1,2-dihydroxybenzene), compared with Fe, Al, and Si oxides (Shindo and Huang, 1982, 1984a; Shindo, 1992; Liu and Huang, 2001; Colarieti et al., 2006). This is partially attributable to the lower electronegativity of Mn (Liu and Huang, 2001). The electronegativity values of Mn, Fe, Al, Si, H, and O are, respectively, 1.55, 1.83, 1.61, 1.90, 2.20, and 3.44 (Porterfield, 1983). Catechol acts as a hard Lewis base, and Mn, Fe, Al, and Si are hard Lewis acids. When Mn, Fe, Al, or Si replace H in catechol to form metal–catechol complexes, the electron cloud delocalizes from the phenolic oxygen into the π-orbital formed from overlap of the 2p orbitals of the aromatic C atoms, thus accelerating the formation of semiquinone-free radicals and their polymerization. The electron cloud around the Mn–O bond in the Mn oxide–phenolic complex should be more delocalized than that around the Al–O bond in the Al–catechol complex and especially the Si–O or Fe–O bond in the Si or Fe oxide–phenolic complex due to the lower electronegativity of Mn than those of Al, Fe, and Si. This provides a partial explanation for the greater accelerating effect of Mn oxide on the humification of catechol than Fe, Al, or Si oxides. Naturally, redox reactions also play an important role in many abiotic catalytic reactions. Aluminum and silicon oxides are not subject to redox reaction. The standard electrode potential ($E°$) values of the overall redox reaction of the Fe(III) oxide–catechol and Mn(IV) oxide–catechol systems are +0.071 V and +0.509 V, respectively, as indicated by the following reactions (Shindo and Huang, 1984a):

$$Fe^{3+} + e^- = Fe^{2+} \quad E° = 0.770\,V, \tag{18.2}$$

$$MnO_2 + 4H^+ + 2e^- = Mn^{2+} + 2H_2O \quad E° = 1.208\,V, \tag{18.3}$$

$$C_6H_4(OH)_2 = C_6H_4O_2 + 2H^+ + 2e^- \quad E° = 0.6992V. \tag{18.4}$$
The positive $E°$ values of the overall redox reactions indicate that the reactions are thermodynamically feasible, and catechol oxidation can thus be accelerated by Fe oxide and especially Mn

oxide. This also explains the stronger catalytic ability of the Mn oxide than Fe, Al, and Si oxides in accelerating catechol oxidation. In addition, the lower point of zero salt effect (PZSE) and more negative charges of the Mn oxide than the Fe and Al oxides could also enhance the oxidation of catechol (Liu and Huang, 2001). A more negatively charged mineral surface may favor the binding of protons released from catechol and subsequently increase the catalytic reaction rate. Therefore, the catalytic ability of a metal oxide in polyphenol transformation depends on the $E°$ value of the overall redox reaction and the ability of the metal ions to complex with ligands, to shift electron density and molecular confrontation in the way conducive to the reaction, and to favor the binding of protons to the metal oxide.

Birnessite strongly promotes the formation of humic macromolecules from pyrogallol (1,2,3-trihydroxybenzene) under environmentally relevant conditions; total yields of humic substances were 10.5-fold higher than in pyrogallol reacted in the absence of birnessite (Wang and Huang, 1992). Manganese(IV) oxide has also been effectively used to treat polyphenol-polluted olive mill wastewater by enhancing humification (polymerization) (Brunetti et al., 2007). The Mn oxide-treated wastewater was found to enhance the humified C content of amended soils and increased the overall fertility of the soil (Brunetti et al., 2007).

During the abiotic catalytic transformation of pyrogallol to HA, Mn(IV), Fe(III), Al, and Si oxides also promote the abiotic generation of CO_2 through their ability to cleave the ring structure of pyrogallol (Wang and Huang, 1992, 2000b). The order of CO_2 release from the oxide-catalyzed pyrogallol reaction systems was Mn(IV) oxide >>> Fe(III) oxide > Al oxide > Si oxide (Wang and Huang, 2000b). The release of CO_2 was related to the development of carboxylic group contents in the HA fraction. Wang and Huang (2000a) showed that the infrared spectrum of the fulvic acid (FA) fraction from the Mn oxide–pyrogallol system closely resembles that of the FA fraction extracted from a natural Borosaprist soil. The abiotic ring cleavage of polyphenols by soil inorganic components may partially account for the findings of the high aliphaticity of natural humic substances (Wilson and Goh, 1977; Hatcher et al., 1981). Lee and Huang (1995) showed that the abiotic release of CO_2 in the birnessite–polyphenol and polyphenol systems increases with light intensity, a consequence of a photofragmentation of polyphenolics catalyzed by birnessite. These findings imply that the pathways of C turnover in the photic zones of soils and aquatic environments may differ from those in their subsurface and submerged layers.

Shindo and Huang (1992) compared the catalytic effects of Mn oxide and the oxidoreductase enzyme, tyrosinase, on the oxidative polymerization of diphenols over the pH range common in soil environments. Manganese oxide influences the oxidative polymerization of hydroquinone and resorcinol to a larger extent than does tyrosinase, whereas the reverse is true for catechol. The yields of HAs are significantly influenced by the kind of catalyst and polyphenol. In the Mn oxide system, the yield of HAs is in the order hydroquinone > catechol > resorcinol. In the tyrosinase system, catechol produces the highest yield of HA, followed by hydroquinone and resorcinol. These findings indicate that the

relative catalytic effects of Mn(IV) oxides and enzymes such as tyrosinase would vary with the type of polyphenols in soils. HAs formed by mineral catalysis have a better defined chemical structure than those formed by enzymatic oxidative polymerization, favoring the formation of components with lower degrees of aromatic ring condensation and lower molecular weights compared with those generated in the presence of tyrosinase (Naidja et al., 1998). Ahn et al. (2006) showed that the presence of the abiotic catalyst birnessite actually inhibits the catechol oxidative polymerization activity of the enzyme laccase, which was attributed to the Mn^{2+} released during the reduction of birnessite by catechol, which binds to the enzyme and alters its active site.

Phenolic acids have been shown to be oxidized rapidly in the presence of MnO_2 to form a number of soluble products (Lehmann and Cheng, 1988). Mass spectrometric data show that some of the soluble products of the reaction have somewhat higher molecular weights than the parent compounds. However, the soluble products of the reaction of ferulic acid and MnO_2 do not contain any ferulic acid hexamers (Liu et al., 1981; Bollag et al., 1982). The oxidized products of ferulic acids are apparently rapidly sorbed on the surfaces of MnO_2. Polyhydroxyphenolic acids with *p*- and *o*-OH groups are rapidly oxidized by Mn oxides (Pohlman and McColl, 1989) (Table 18.2) to polymeric humic products in both soil and Mn suspensions. On the other hand, *m*-polyhydroxyphenolic acids are not readily oxidized.

Monophenolic compounds, such as phenol (Jung et al., 2008b), and particularly those containing electron-donating substituent groups on the aromatic ring, can be oxidatively transformed by Mn(IV) oxides (Lehmann et al., 1987; Stone, 1987; Ulrich and Stone, 1989; Zhao et al., 2006). Manganese(IV) oxide has been found to be an effective abiotic catalyst of the oxidative transformation of highly toxic and recalcitrant compound, pentachlorophenol (PCP), under aquifer (Petrie et al., 2002) and near-dry

TABLE 18.2 Kinetic Constants for Polyhydroxyphenolic Acid Oxidation by Soil and Manganese Oxide Suspension[a]

Compound	Rate Constants (L mol^{-1} s^{-1})	
	Challenge A Horizon	MnO$_2$
2,3-Dihydroxybenzoic acid	ND[b]	0.03
2,5-Dihydroxybenzoic acid	0.06	0.04
2,6-Dihydroxybenzoic acid	0.00[c]	ND
3,4-Dihydroxybenzoic acid	0.10	0.04
3,5-Dihydroxybenzoic acid	0.00	0.00

[c] No oxidation of phenolic acid within 120 min of reaction.

conditions (Pizzigallo et al., 2004). Pyrolusite is able to oxidatively degrade the carcinogenic pesticide and antiseptic agent TCP (2,4,6-trichlorophenol) under near-dry conditions; however, the transformation products may actually be more toxic and persistent than the parent compound (Smith et al., 2006). Methoxylyated phenols have been used to mediate the oxidative polymerization of the nonphenolic fungicide, cyprodinil (4-cyclopropyl-6-methyl-*N*-phenyl-2-pyrimidinamine), in the presence of birnessite (Kang et al., 2004). Birnessite-induced oxidative coupling also results in the decarboxylation, demethoxylation, and dehalogenation of substituted phenolic subtrates (Dec et al., 2001, 2003). Electron-withdrawing substituents, such as –COOH and –Cl, are more susceptible to release than electron-donating ones, such as –OCH$_3$ and –CH$_3$ (Dec et al., 2003).

The catalytic ability of Fe oxides in the rapid oxidative polymerization of polyphenols (Scheffer et al., 1959) increases in the following order: ferrihydrite > goethite > maghemite > lepidocrocite > hematite. Ferrihydrite, which is SRO Fe oxide with high surface area, is most reactive in catalyzing the oxidative polymerization reaction. Besides the nature of Fe oxides, the catalytic ability of Fe is related to structure and functionality of phenolic compounds (Shindo and Huang, 1984a; Shindo, 1992; Pracht et al., 2001).

The oxidative polymerization of polyphenols is substantially influenced by the catalysis of Al hydroxides (Wang et al., 1983). Soluble silicic acid in aqueous solution and precipitated short-range order silica can catalyze the oxidation of polyphenols (Ziechmann, 1959). Liu and Huang (2000) reported that silicic acid and especially hydroxyl Al ions substantially enhance oxidative polymerization of catechol. Liu and Huang (2002) showed that hydroxy-aluminosilicate ions, which are precursors to noncrystalline aluminosilicates, are also effective in promoting the oxidative polymerization of catechol. The surface of ground quartz has a disturbed layer, which is SRO in nature (Iler, 1979). Similar disturbed surface layers are present on quartz grains in soils (Ribault, 1971). Oxidative polymerization of polyphenols may be catalyzed by the disturbed surface of quartz in soils.

Besides metal oxides, clay size layer silicates have the ability to catalyze the oxidative transformation of polyphenols. Before the pioneering work on the catalytic role of clay size layer silicates in oxidative polymerization of phenolic compounds and the subsequent formation of humic substances (Kumada and Kato, 1970; Filip et al., 1977; Wang and Li, 1977), the conversion of many aromatic amines into their color derivatives by clay minerals and clays had been investigated (Faust, 1940; Hauser and Legget, 1940). Solomon (1968) reported that, except for talc, a large number of representative minerals produce a blue color of varying intensity when brought into contact with a saturated solution of benzidine hydrochloride. The active sites for the oxidation of benzidine are located on the crystal edges and on transition metal atoms in the higher oxidation state that occupy octahedral sites in the silicate layers. Thompson and Moll (1973) measured the oxidative power of smectites by oxidation of hydroquinone to *p*-benzoquinone in a clay slurry. Oxidation occurs

in the presence of O_2 (air), but not N_2 unless Fe^{3+} or Cu^{2+} are the exchangeable cations. Adsorbed O_2 molecules or radicals on the clay surface are apparently partially responsible for the oxidation.

Pinnavais et al. (1974) reported aromatic radical cation formation on the intracrystal surfaces of transition metal-saturated layer silicates. Aromatic molecules, when reacted under very moderated conditions with Cu(II) or Fe(II) ions, may donate electrons to the metal cations, leading to the formation of polymers (Mortland and Halloran, 1976). Montmorillonite, vermiculite, illite, and kaolinite accelerate the formation of HAs to varying degrees (Shindo and Huang, 1985a). The promoting effect of 2:1 layer silicates is higher than that of 1:1 layer silicates because of the larger specific surface and lattice imperfections, which favor adsorption of O_2 molecules or radicals.

One of the well-identified precursors (Flaig et al., 1975; Hayes and Swift, 1978) for the formation of humic substances, hydroquinone, can be transformed in aqueous solution at near-neutral pH (6.5) to humic macromolecules and deposited in the interlayers of nontronite saturated with Ca, which is the most common and most abundant exchangeable cation in soils and sediments (Wang and Huang, 1986). Most of the interlayer humic macromolecules are highly resistant to alkali extraction and may, thus, be humin-type materials. Therefore, besides Al interlayers in 2:1 expansible layer silicates, the formation of humic substance interlayers in 2:1 expansible layer silicates, through polymerization of phenol monomers and the associated reactions in soils and sediments, deserves close attention.

The ability of nontronite to promote the oxidation of polyphenols is related to the structure and functionality of the polyphenols, and part of the reaction process may proceed as shown below (Wang and Huang, 1994):

$$(18.5)$$

$$(18.6)$$

$$(18.7)$$
Catechol with two *o*-OHs is evidently more easily cleaved than hydroquinone with two *p*-OHs while pyrogallol with three hydroxyls in adjacent positions is even more easily cleaved than

catechol. The resultant carboxyl group-containing intermediates are further oxidized to form CO_2 and aliphatic fragments. In the reaction systems, intermediate products and aliphatic fragments may form polycondensates. The structure and functionality of polyphenols thus have an important role in influencing the extent of catalytic transformations by nontronite.

Primary minerals, which are commonly present in soil environments (Dixon and Weed, 1989), can catalyze the oxidative polymerization of polyphenols (Shindo and Huang, 1985b). The degree of acceleration of the oxidative polymerization of hydroquinone is greatest in the tephroite system, which increases the total HA yields more than ninefold because (1) tephroite (ideal chemical formula, $MnSiO_4$) is a Mn-bearing silicate, (2) part of the Mn in tephroite is present in the higher valence states, and (3) the oxidation of diphenols $[C_6H_4(OH)_2]$ by Mn(III) and Mn(IV) is thermodynamically favorable (Lide, 2008).

The hydroquinone-derived polymers with molecular weights of approximately 3500 and higher formed in the presence of the tephroite system (Shindo and Huang, 1985b) have similar IR absorption bands to those of humic substances (Schnitzer, 1978). The surface features of these polymers (Figure 18.1) are similar to those of soil HA and FA (Stevenson and Schnitzer, 1982) with the smallest discrete particles being spheroids with diameters of 0.1–0.2 µm (Figure 18.1a) and some aggregation of individual spheroids (Figure 18.1b and c). Small aggregates (Figure 18.1c) resemble moss while the large aggregates are nodule like (1–5 µm diameter) and doughnut like (6–8 µm diameter) (Figure 18.1a and b). The polymers do not appear to be associated with the surfaces of tephroite particles (Figure 18.1d). Consequently, the role of primary minerals in the oxidative polymerization of polyphenols and the subsequent formation of humic substances in soils should not be overlooked (Shindo and Huang, 1985b).

SRO aluminosilicates, such as allophone, are known to act as catalysts in the oxidative degradation of polyphenols (Kyuma and Kawaguchi, 1964; Kumada and Kato, 1970). Hydroxy-aluminosilicate ions (proto-imogolite sol) also have the ability to catalyze polyphenol humification (Liu and Huang, 2002). However, the role of other SRO aluminosilicates remains obscure. On the other hand, the formation of SRO aluminosilicates is significantly affected by inorganic ligands, low-molecular-weight organic acids, humic substances, metallic cations, and expansible layer silicates (Huang, 1991a), resulting in the formation of ill-defined aluminosilicate complexes and hydroxyaluminosilicate-intercalated layer silicates. The catalytic ability of these SRO mineral colloids in the transformation of polyphenols and other organic compounds in soils has yet to be investigated.

18.3.1.2 Other Organic Compounds

Many naturally occurring organic acids, including salicylic, pyruvic, oxalic, and malic acids, are degraded by mineral colloids such as Mn oxides by electron transfer reactions (Stone and Morgan, 1984a, 1984b). A wide range of nonphenolic xenobiotic compounds, including pesticides, antibiotics, dyes, and
FIGURE 18.1 SEM micrographs of hydroquinone polymers in the supernatant and mineral particles settled in the tephroite system at the ratio of mineral to hydroquinone solution of 0.01 at the initial pH of 6.0 at the end of 7 days. Huang. 1985b. Catalytic polymerization of hydroquinone by primary minerals. Soil Sci. 139:505–511.)

explosives, are subject to abiotic soil mineral-catalyzed oxidative transformation. Abiotic degradation pathways of biocides (pesticides and antibiotics) are particularly important in the environment as the toxicity of these substances can limit their biotic degradation.

18.3.1.2.1 Pesticides

Manganese(IV) oxides are able to catalyze the oxidative polymerization of toxic anilines, chloroanilines, and other aromatic amines, which originate from pesticides, as well as from chemical manufacturing residues (Laha and Luthy, 1990; Pizzigallo et al., 1998; Li et al., 2003). Birnessite is an effective solid-state catalyst of the breakdown of organic pollutants such as the herbicide 2,4-D (2,4-dichlorophenoxyacetic acid) and diethyl ether, which are adsorbed on birnessite and rapidly oxidized (Cheney et al., 1996), both producing CO_2 as a major product, but by somewhat different mechanisms. Nasser et al. (2000) demonstrated a dry mechanochemical technique for quickly and completely degrading 2,4-D by lightly grinding it with birnessite, thus eliminating the need for organic solvents such as diethyl ether. The widely used herbicide atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine) is also partially degraded by mechanochemical contact with Mn(IV) oxides (birnessite, cryptomelane, and pyrolusite) via N-dealkylation and subsequent

decarboxylation mechanisms (Shin et al., 2000). The removal of 4-chloroaniline and PCP by a mechanochemical procedure was far more effective than by batch contact (solution) in the presence of birnessite and ferrihydrite (Pizzigallo et al., 2004). The mechanochemical contact of polychlorinated biphenyls (PCBs) and birnessite produced a removal of pollutant that was a function of the number of chlorine atoms, that is, the more the chlorine atoms the less effective the oxidative degradation (Pizzigallo et al., 2004). Possible contributions of solid-state degradation to herbicide breakdown by abiotic catalysis should be considered in modeling herbicide breakdown or when designing experiments for soil remediation.

Birnessite is able to oxidatively degrade glyphosphate (*N*-phosphonomethyl-glycine), which is the most commonly used pesticide worldwide (Barrett and McBride, 2005). The abiotic degradation mechanism involves C–P and C–N bond cleavage of glyphosphate and its degradation product, sarcosine, due to electron transfer reactions at the Mn oxide surface (Figure 18.2; Barrett and McBride, 2005). Pyrolusite is able to effectively oxidatively degrade the widely found organic pollutant 2-mercaptobenzothiazole (a biocide and compound used in manufacture of rubber) into SO_4^{2-} and NO_3^-; however, the presence of organic acids, carboxylic acids (oxalic, citric, tartaric, and malic acids), or metal ions (Ni^{2+}, Ca^{2+}, Mn^{2+}, and Cr^{3+}) has an inhibiting effect on the rate of degradation (Li et al., 2008).

Clay-catalyzed nitration of a carbamate fungicide diethofencarb. J. Agric. Food Chem. 51:7730–7737. Copyright 2003 American Chemical Society.)

Clay minerals, kaolinite and montmorillonite, are able to catalyze the nitration of the carbamate fungicide, diethofencarb (isopropyl 3,4-diethoxycarbanilate), which most likely proceeds through the formation of $NO_2^\bullet$ radicals on the surface of the clay (Figure 18.3). The similar nitration of the phenyl ring of the pesticide, famoxadone (3-anilino-5-methyl-5- (4-phenoxyphenyl)-1,3-oxazolidine-2,4-dione), has been reported (Jernberg and Philip, 1999). Nitration of pesticides is only known as a clay-catalyzed reaction (Nikalje et al., 2000).

18.3.1.2.2 Antibiotics

Manganese(IV) oxides are able to oxidatively degrade many of the leading groups of antibacterial agents used in the treatment of humans and animals, in livestock feed additives, or in active ingredients in personal care products (Zhang et al., 2008).

Manganese(IV) oxide is able to catalyze the oxidative degradation of the popular and potent fluoroquinolone (FQ) antibiotic agents under environmental conditions (Zhang and Huang, 2005a). The oxidative degradation mechanism (Figure 18.4) involves a surface reaction mechanism that likely begins with the formation of a surface complex between FQ and the surface-bound Mn(IV), followed by oxidation at the aromatic N1 atom of FQ's piperazine moiety to generate an anilinyl radical intermediate. The radical intermediates subsequently undergo N-dealkylation, C-hydroxylation, and possibly coupling to yield a range of products. The δ-MnO_2 exhibited reactivity to the FQ antibiotics in the order of ciprofloxacin ≈ enrofloxacin ≈ norfloxacin ≈ ofloxacin > lomefloxacin > pipemidic acid ≫ flumequine (Zhang and Huang, 2005a). The veterinary N-oxide antibiotics, carbadox, olaquindox, quinoline N-oxide, and quindoxin also exhibit high oxidation reactivity toward MnO_2 (Zhang and Huang, 2005b). The transformation mechanism involves the formation of an N-oxide radical intermediate and the generation of Mn(II) (Zhang and Huang, 2005b).

Manganese(IV) oxides are also able to promote the appreciable degradation of tetracycline antibiotics (Rubert and Pedersen, 2006). Reactivity of tetracycline antibiotics toward MnO_2 increases in the following order: rolitetracyline ≈ oxytetracycline ≤ tetracycline ≈ meclocycline < chlortetracycline. Abiotic degradation of the veterinary ionophore and macroclide antibiotics, monensin and tylosin, does take place in soil, however at a much slower rate than by microbial degradation in soil (Sassman and Lee, 2007; Sassman et al., 2007).

18.3.1.2.3 Explosives and Dyes

The explosive CL-20 (hexanitrohexaazaisowurtzitane) was found to be quickly (in minutes) abiotically, and oxidatively degraded in the presence of 2:1 layer silicates (montmorillonite, hectorite, and nontronite), micas (biotite and illite), and birnessite (Szecsody et al., 2004). The exact mechanism remains unclear, but it is known that the cage structure of CL-20 is broken and that cleavage of C–C and C–N bonds occurs due to the formation of nitrite and formate anions (Szecsody et al., 2004). Birnessite has also been found to effectively catalyze the complete abiotic transformation of the Fe^0-induced reduction products of the explosive 2,4,6-trinitrotoluene (TNT) via oxidative-coupling reactions (Kang et al., 2006).

Magnetite and other mixed metal (Co, Cu, and Mn)-ferrite oxides are able to efficiently catalyze the oxidative degradation and decolorization of various dyes (bromophenol blue, Chicago sky blue, Cu-phthalocyanine, eosin yellowish, Evans blue, naphthol blue black, phenol red, poly B-411, and reactive orange 16) in the presence of hydrogen peroxide by generating hydroxyl-free radicals (Baldrian et al., 2006). The metal oxide catalysts are

FIGURE 18.4   Proposed reaction scheme for oxidation of fluoroquinolone antibiotics by δ-MnO$_2$. (Reprinted with permission from Zhang, H.C., and C.H. Huang. 2005a. Oxidative transformation of fluoroquinolone antibacterial agents and structurally related amines by manganese oxide. Environ. Sci. Technol. 39:4474–4483. Copyright 2005 American Chemical Society.)

able to retain their activity even after repeated catalytic cycles and over a broad pH range unlike enzymatic catalysts such as laccase (Baldrian et al., 2006). The ferric iron species in layer silicate clays are also able to catalyze the oxidative degradation of the organic dye, malachite green, in the presence of hydrogen peroxide (Cheng et al., 2008). The exchangeable interlayer Fe(III) ions exhibit a much higher reactivity than structural Fe(III) in the octahedral sheet. The Fe-containing clays are chemically and mechanically stable, and no loss of activity was observed after 14 recycles (Cheng et al., 2008).

18.3.2 Polycondensation of Phenolic Compounds and Amino Acids

The transformation of colorless amino acids and polyphenols by quinone–amino acid polycondensation reactions into darkly colored polymers is a significant browning reaction in nature (Bittner, 2006). Birnessite efficiently catalyzes the polycondensation of phenolic compounds and amino acids such as in hydroquinone–glycine systems in the common pH range (4–8) of soils

with the formation of NH$_3$–N and nitrogenous polymers (Table 18.3). The proposed processes are as follows: (1) the Mn oxide acts as Lewis acid by accepting electrons from hydroquinone, which is thus oxidized and subsequently polymerized; (2) the products of the reaction of glycine with hydroquinone polymerize to form nitrogenous polymers, thereby incorporating glycine into the polymers during the oxidative polymerization of hydroquinone; and (3) a partial deamination of glycine occurs during the second process.

Birnessite also catalyzes the polycondensation of glycine and pyrogallol and deamination and decarboxylation of glycine especially in the presence of pyrogallol (Wang and Huang, 1987). The formation of HA and FA is not evident in the presence of glycine alone. In a N$_2$ atmosphere, CO$_2$ release in the birnessite–glycine–pyrogallol system is drastically reduced. Birnessite also greatly enhances the formation of N-containing humic polymers. Most of the released NH$_3$ can be attributed to the deamination of glycine by pyrogallol-derived free radicals as catalyzed by birnessite but an appreciable amount can also be directly derived from the deamination of glycine by birnessite.

TABLE 18.3   Formation of NH$_3$–N and Polymer–N (in mg kg^{-1}) in the Hydroquinone–Glycine System Both in the Absence and Presence of Mn Oxide at Different pH Values at the End of 24 h

	Initial pH of 4.0				Initial pH of 6.0				Initial pH of 7.3			
	Final pH	NH$_3$–N	Polymer–N	Sum-N	Final pH	NH$_3$–N	Polymer–N	Sum-N	Final pH	NH$_3$–N	Polymer–N	Sum-N

Carbon-14 labeling of glycine was used to measure the extent of incorporation of carboxyl C and alkyl C into the polycondensates of pyrogallol and glycine (Wang and Huang, 1997). Birnessite promotes the incorporation of carboxyl and especially alkyl C of glycine into the polycondensates formed in the presence of pyrogallol (Wang and Huang, 1997, 2005). The results indicate that the formation of the C–C bond is more prevalent than that of the C–O bond in the polycondensation of glycine and pyrogallol catalyzed by birnessite.

Besides birnessite, clay size layer silicates also have the ability to catalyze the polycondensation of phenolic compounds and amino acids. Wang et al. (1985) show the catalytic effect of Ca-illite on the formation of N-containing HAs in the systems containing phenolic compounds and amino acids at neutral pH. The yields and N contents of the synthesized HAs depend on the nature of amino acids.

Nontronite in which structural Fe(III) acts as an electron acceptor analogous to Mn(IV) in MnO_2 (Solomon, 1968; Theng, 1974) also catalyzes the polycondensation of glycine and pyrogallol (Wang and Huang, 1991). The IR and electron spin resonance (ESR) spectra of the HA and FA formed, which show the presence of a stabilized organic free radical (semiquinone), are similar to those of natural soil HA and FA (Schnitzer, 1977; Senesi and Schnitzer, 1977; Schnitzer and Levesque, 1979; Hatcher et al., 1980; Schnitzer and Ghosh, 1982). The formation of semiquinone-free radicals appears to proceed through electron transfer from pyrogallol to Fe(III) or other variable-valence transition metal ions on the edges or in the nontronite structure (Solomon, 1968). Electrons diffuse or tunnel to octahedral sites from layer edges or basal surfaces (Tennakoon et al., 1974). The strong oxidation power of chemisorbed O_2 on silicates (Solomon and Hawthorne, 1983) such as nontronite seems to cause the ring cleavage of pyrogallol and the decarboxylation and deamination of glycine (Wang and Huang, 1991). Semiquinone-free radicals, aliphatic fragments, and glycine apparently undergo polycondensation to form humic polymers.

Natural soil clays, from temperate and tropical environments, have been shown to catalyze the polycondensation of pyrogallol and glycine, the ring cleavage of pyrogallol, its polymerization, and the deamination of glycine (Wang and Huang, 2003). The reactivity of the mollisol and oxisol clays was attributed to the catalysis of the layer silicates and oxides of Fe, Al, and Mn present in the natural soil clays (Wang and Huang, 2003).

18.3.3 The Maillard Reaction and Integrated Polyphenol–Maillard Reactions

The Maillard reaction (Maillard, 1913), involving condensation reactions between reducing sugars and amino acids, is considered to be an important pathway in natural humification (Ikan et al., 1996). Sugars and amino acids are among the most abundant constituents of terrestrial and aquatic environments (Anderson et al., 1989). The Maillard reaction involves numerous reactions between the degradation products of the precursor sugars and amino acids, and reaction intermediates, known as Amadori and Heyns compounds (Yaylayan, 1997).

The initial reaction in the Maillard reaction involves condensation between the α-hydroxy carbonyl group of a reducing sugar and the amino group from an amino acid with the formation of a Schiff base, which rearranges to form either Amadori or Heyns compounds. Aldohexoses generate Amadori compounds while ketohexoses generate Heyns products (Yaylayan, 1997). These compounds can undergo retroaldolization reactions forming α-dicarbonyl and α-hydroxyketone compounds. All these compounds are highly reactive and readily polymerize in the presence of amino compounds to form brown-colored melanoidins. Amino acids can react with the α-dicarbonyl compounds, undergoing the Strecker degradation and then forming α-amino ketones. The α-amino ketones may then condense resulting in the formation of pyrazines (Ho, 1996; Yaylayan, 1997). In addition, the Maillard reaction can result in the formation of polyphenols, such as catechol, resorcinol, hydroquinone, and pyrogallol, which can enhance the degree of browning during the Maillard reaction by affecting the redox potential of the system (Haffenden and Yaylayan, 2005) and undergoing polymerization and polycondensation (Wang and Huang, 2005).

Commonly found soil metal oxides, birnessite (Jokic et al., 2001b), goethite (Gonzalez and Laird, 2004), and smectite clays (Gonzalez and Laird, 2004), have been shown to catalyze the Maillard reaction under typical pH and temperature ranges found in the natural environment. Jokic et al. (2001b) were the first to report that birnessite catalyzes the Maillard reaction between glucose and glycine. Their data showed that the presence of a redox-reactive mineral, namely, birnessite, significantly accelerates the reaction by one to two orders of magnitude under environmentally relevant temperatures (25°C and 45°C) and a neutral pH (7.00). This reaction is kinetically sluggish under ambient temperatures (Jokic et al., 2001c) but the presence of birnessite significantly catalyzes the reaction by decreasing the activation energy required. Other groups (Bosetto et al., 1995, 1997; Arafaioli et al., 1997, 1999) have also investigated the clay mineral catalysis of the Maillard reaction between various amino acids and glucose at relatively high temperatures (at 70°C).

Light enhances birnessite catalysis of the Maillard reaction, but the reaction still proceeds in the absence of light (Jokic et al., 2001a). This means that the reaction could readily occur in the subsoil in the presence of a mineral catalyst such as birnessite. The Maillard reaction between glucose and glycine as catalyzed by birnessite results in the formation of humic substances that contain significant amounts of (1) amides, which are the dominant N types in humic substances, soils, and sediments, and (2) heterocyclic N compounds, which are often referred to as *unknown* N (Jokic et al., 2004a) (Figure 18.5). The mineral-catalyzed Maillard reaction provides a possible explanation for one of the pathways for the formation of heterocyclic and amide N found in humic substances in the environment (Jokic et al., 2004a). The action of birnessite on glucose should promote the autoxidation of glucose, which results in the
FIGURE 18.5 N 1s XANES spectra of (a) fulvic acid isolated from a glucose–glycine–δ-MnO$_2$ system and (b) the lyophilized solid phase. The peaks are assigned to pyridinic (398.6 eV), pyridone (400.7 eV), amide (401.3 eV), and pyrrolic (402.0 eV) moieties. (Reprinted from Jokic, A., H.-R. Schulten, J.N. Cutler, M. Schnitzer, and P.M. generation of reactive dicarbonyl compounds, hydrogen peroxide, and hydroxylating agents (Wolff, 1996). These reactive dicarbonyl compounds would then react with ammonia formed by the known deamination of glycine catalyzed by birnessite (Wang and Huang, 1987), as proposed by Vairavamurthy and Wang (2002) or with glycine (undergoing the Strecker degradation), resulting in either case in the formation of heterocyclic N compounds (Wong and Shibamoto, 1996). Ammonium ions are known to react with compounds containing reactive carboxyl groups to form pyridinic structures (Steelink, 1994). Carboxylic acids are produced during the Strecker degradation of amino acids (Wong and Shibamoto, 1996) or by the action of manganese dioxides on simple carbohydrates (Bose et al., 1959; Gonzalez and Laird, 2006). When heated, carboxylic acids react with ammonia to form amides (Smith and March, 2001). The scheme for possible amide formation is shown in Figure 18.6.

Gonzalez and Laird (2004) showed that four different smectites saturated with various metal cations (Ca, Na, Cu(II), and Al) could catalyze the Maillard reaction between arginine and glucose at an environmentally relevant temperature (37°C). They found that only saturation with Cu(II) significantly altered the amount of humic substances produced. They also observed that some of the adsorbed humic substances were intercalated into the smectites.

Jokic et al. (2004b) were the first to study an integrated Maillard reaction and polyphenol (glucose, glycine, and catechol) pathway of humification, using birnessite as catalyst. Their data showed that birnessite significantly accelerates humification processes in an integrated polyphenol–Maillard reaction system under ambient conditions (25°C and 45°C). In nature, it is likely that the Maillard reaction and polyphenol pathways interact closely, since sugars, amino acids, and polyphenols coexist in soil solutions and natural waters. Jokic et al. (2004b) also showed that the integrated polyphenol–Maillard reaction system is more effective in generating humic polymers than the Maillard reaction alone. The type of polyphenol and the molar ratio of polyphenol to Maillard reagents in the polyphenol–Maillard reaction system significantly affect not only the humification processes but also the biomolecule-induced formation of inorganic C, namely, rhodochrosite (MnCO$_3$) (Hardie et al., 2009). Increasing the molar ratio of polyphenols to Maillard reagents results in a significant enhancement of humification in the polyphenol–Maillard reaction in the presence of birnessite. Polyphenols with *ortho*-OH groups (pyrogallol) participate in direct electron transfer reactions with birnessite more readily than polyphenols with *meta*-OH groups (resorcinol), and subsequently undergo oxidative polymerization and ring-cleavage reactions to a greater extent. Thus, the humic polymers formed in the pyrogallol–Maillard system are significantly more aliphatic in character than those formed in the resorcinol–Maillard system. Furthermore, the greater extent of polymerization reactions in the birnessite-catalyzed pyrogallol–Maillard system results in the suppression of MnCO$_3$ formation. Hardie et al. (2007) also compared the HA fraction formed in the presence of birnessite from the Maillard reaction and two

polyphenol–Maillard reaction systems with natural soil and peat HA using C K-edge NEXAFS and found that these HAs are basically similar, especially the HA from the Maillard reaction and pyrogallol–Maillard systems.

18.3.4 Surface Brønsted and Lewis Acidity and Hydrolysis of Organic Compounds

Mineral colloids may detoxify adsorbed pesticides by catalyzing their decompositions through the ability of mineral colloids to behave as Brønsted acids and donate protons or to act as Lewis acids and accept electron pairs. Brønsted acidity derives essentially from the dissociation of water molecules coordinated to surface-bound cations, resulting in the formation of active protons. This acidity is, thus, strongly influenced by the hydration status and polarizing power of surface-bound and structural cations on mineral colloids (Mortland, 1970, 1986). Low water contents and highly polarizing cations (small, high charge) promote Brønsted acidity. Lewis acidity arises from constituent ions such as Al and Fe ions exposed at the edges of mineral colloids (Sposito, 1984; McBride, 1994).

Many uncharged organic molecules that require extremely acid conditions to accept a H^+ ion in solution can be protonated on the surface of mineral colloids (Huang, 1990; McBride, 1994). The Brønsted acid strength and the degree of protonation are related to the electronegativity and polarizing power of the exchangeable and structural metal cations in the following order (McBride, 1994): $H^+ > Al^{3+}$, $Fe^{3+} > Mg^{2+} > Ca^{2+} > Na^+ > K^+$. As clay surfaces become drier, the Brønsted acidity increases and protons are concentrated in a smaller volume of water resulting in more extreme surface acidity. Even very weak bases, that is, poor proton acceptors can be protonated on the surfaces of such mineral colloids.

The degradation of certain pesticides is catalyzed as the result of their adsorption on mineral colloids, which was first observed by formulation chemists who used clays as carriers and diluents (Fowkes et al., 1960). Surface-catalyzed degradation of pesticides on clays was later demonstrated for several organophosphate and *s*-triazine pesticides and has been attributed to the surface acidity of clay minerals (Brown and White, 1969; Salztman et al., 1974; Minglegrin et al., 1977). Minglegrin and Salztman (1979) demonstrated that the nature of the clay, its saturating cation, and hydration status determine the rate and mechanism of degradation of parathion. The adsorption-catalyzed degradation of parathion is a hydrolysis reaction that proceeds either directly or through a rearrangement step.

Magnesium-saturated montmorillonite converts the amino form of 3-aminotriazole to the imino form (Russell et al., 1968a) as shown below:

$$(18.8)$$
Triazine compounds can also be protonated on dry mineral colloids. Armstrong et al. (1967) showed that the addition of sterilized soil to atrazine solution increased the hydrolysis rate of atrazine 10-fold. Soil catalytic degradation of atrazine through hydrolysis is an important pathway. Mineral surface acidity also catalyzes hydrolysis of the chloro-*s*-triazine herbicides to the nonphytotoxic 2-hydroxy-*s*-triazines (Russell et al., 1968b) and may be of significance in a wide range of other organic compounds (McBride, 1994).

Besides the Brønsted acid, the Lewis acid properties of metals appear to be of significance in mineral-catalyzed hydrolysis reactions. The oxides of Fe and Al in water, and especially in the dry state, have some catalytic function in organic hydrolysis reactions, at least for those that are known to be hydroxyl ion catalyzed (Hoffmann, 1990). Those hydrolyzable organics that have a suitable structure to chelate with the surface metal cations are, in general, the most susceptible to mineral-catalyzed degradation.

Dissolved metals and metal-containing surfaces play an important role in catalyzing the hydrolysis of organic pollutants. The catalytic effectiveness of a metal ion depends on its ability to complex reactant molecules (e.g., ester linkage, leaving group, and attacking nucleophile) and shift electron density and conformation in ways favorable to reaction (Hoffmann, 1980). Metals vary in their complex formation constants, which reflect difference in metal–ligand bond strengths and solvation forces. The following rules can explain the general features: (1) complex formation constants generally increase as the charge to radius ratio of the metal ion is increased, because the electrostatic contribution to bond formation is increased; (2) polarizable metals and ligands gain additional complex stability through covalent bond formation; and (3) as complex formation constants increase, competition for the metal among available ligands (including OH^- and other inorganic constituents) becomes more pronounced. Trivalent metals such as Al and Fe(III) and tetravalent metals such as Ti(IV) are classic hard metals, which form strong complexes with classic hard ligands (Pearson, 1966). Organic compounds possessing O and N donor atoms are classified as hard ligands, whereas those possessing S donor atoms are classified as soft ligands. Oxygen donor organic ligands form strong complexes with metals such as Al, Fe(III), and Ti(IV). However, they compete with hydroxo (OH^-) and oxo (O^{2-}) species that limit metal solubility near-neutral pH values. Although Ca^{2+} and Mg^{2+} are also classified as "hard" metals, their s and p orbitals form bonds that are primarily ionic in nature (Stone and Torrents, 1995).

Complex formation constants of metals with a ligand primarily vary with the ionic radius of metals, although increases in polarizability with increasing atomic number are also important (Houghton, 1979). Even if differences in metal–ligand complex formation constants are taken into consideration, differences in electronic structure cause some metals to emerge as particularly effective catalysts.

Metals can form a series of metal hydroxo complexes (Bases and Mesmer, 1986). Although metal hydroxo complexes are less reactive nucleophiles than hydroxide ions, their concentrations can be substantially higher, especially in the neutral to acidic

pH range. Because the pK_1 values for strong Lewis acid metals are low, they generate hydroxo species across a wider pH range. The nucleophiles of various metal hydroxo complexes are governed by pK_1 and the polarizability of the metal (Stone and Torrents, 1995).

The reactivity of hydrolyzable organic pollutants arises from the presence of electrophilic (electron deficient) sites within the molecules (Stone and Torrents, 1995). The S_N2 mechanism (neucleophilic substitution) involves attack of the electrophilic sites by OH^- or H_2O, generation of a higher coordination number intermediate, subsequent elimination of the leaving group, and the formation of a hydrolysis product:

S_N2

$$(18.9)$$
In the case of the S_N1 mechanism (nucleophilic substitution monomolecular), the reaction proceeds with the loss of the leaving group to generate a lower coordination number intermediate and then followed by generation of the hydrolysis product by nucleophilic addition as shown below:

S_N1

$$(18.10)$$
It is generally accepted that metal ions can catalyze hydrolysis in a way similar to acid catalysis. Metal ions and protons coordinate to the pollutants so that electron density is shifted away from the site of nucleophilic attack to facilitate the reaction. Because protons have an extremely high charge density and great polarizing power, metal catalysis is insignificant in acidic solutions. However, metal ions can readily coordinate two or more ligand donor sites on a molecule and can greatly outnumber protons in neutral and alkaline conditions (Plastourgou and Hoffmann, 1984). A list of metal catalysis mechanisms is given in Table 18.4.

The hydrolysis of compounds possessing good leaving groups is limited by the rate of nucleophilic attack. These compounds are susceptible to types 1, 3, 4, 6, and possibly 5 of metal *catalysis*. The hydrolysis of compounds possessing poor leaving groups is limited by the breakdown of the tetragonal intermediate; therefore, types 2, 7, and possibly 5 are important. A number of pesticides and other pollutants are in the intermediate region, where metal catalysis may shift the rate-limiting step from nucleophilic attack to breakdown of the tetrahedral intermediate or vice versa.

Many organic compounds are susceptible to metal ion catalysis. These include carboxylic acid esters, amides, anilides, phosphate-containing esters, and other hydrolyzable compounds

TABLE 18.4 Mechanisms of Metal Catalysis

Type 1	The metal coordinates the electrophile, shifting the electronic distribution in the molecule in a way that enhances its reactivity
Type 2	The metal coordinates to the leaving group, increasing its leaving ability
Type 3	The metal acts as a center for simultaneous attachment of both the electrophile and attacking nucleophile (template effect)
Type 4	The metal coordinates the nucleophile and induces deprotonation (which increases the reactivity of the nucleophile)
Type 5	Coordination of the substrate with the metal induces confirmation changes that facilitate reaction
Type 6	Coordination of the substrate with the metal makes the molecule more positive, lessening unfavorable electrostatic interaction with the nucleophile
Type 7	Coordination with the metal blocks inhibitory reverse reaction paths, such as (1) loss of OH^- from a tetrahedral intermediate instead of loss of the leaving group X^- or (2) nucleophilic attack by X^-

(Stone and Torrents, 1995). In the mid-1950s, the catalytic ability of metals in hydrolysis of thionophosphate pesticides such as parathion and EPN (thionobenzene phosphoric acid *O*-ethyl-*O*-*p*-nitrophenyl ester) was recognized (Ketelaar et al., 1956). Rate enhancements arising from the addition of 1.0×10^{-4} mol L^{-1} Cu^{2+} are as high as 20-fold for parathion at pH 8.5 and 48-fold for EPN at pH 8.2. Coordination of the S donor group by Cu^{2+} activates the P center to nucleophilic attack (type 1 catalysis). Chlorpyrifos, a phosphorothionate pesticide, contains a pyridyl N capable of forming a six-membered chelate ring with the Cu^{2+} ion (Blanchet and St.-George, 1982).

Metal ion catalysis arises from the increased electrophilicity of the P atoms in the chelate ring (type 1 catalysis) (Blanchet and St.-George, 1982) and from possible leaving group effects (type 2 catalysis). Copper(II) is by far the most reactive catalyst among a number of metals [including Mg(II) and Al(III)], which have been observed to catalyze chlorpyrifos hydrolysis. However, Cu^{2+} concentration would have to exceed 10^{-5} mol L^{-1}, which seldom occurs in soil solutions and other natural waters, in order for the metal-catalyzed pathway to surpass the rate of the uncatalyzed hydrolysis pathway (Mill and Mabey, 1988).

Many metals, which are potentially catalytic, form low-solubility inorganic solids within the pH domain of soils and associated environments. Therefore, surface-bound metals must be accessible to reactants in order for a metal-catalyzed effect to be observed. Since the mid-1950s, research has established that metal oxide/hydroxide precipitates act as hydrolysis catalysts for phosphate esters (Butcher and Westheimer, 1955; Wilkins, 1991). Much has been subsequently learned about the chemical properties and reactivities of naturally occurring solids such as oxides, carbonates, sulfides, and aluminosilicates (Stone and Torrents, 1995; Smolen and Stone, 1998).

Complex formation equilibria among dissolved and surface-bound metal species are similar in many aspects. Surface complex formation constants for the metal ions and organic ligands increase in magnitude as the formation constants of analogous complexes in solution are increased (Kummert and Stumm, 1980; Stumm et al., 1980; Davis and Hayes, 1986). Attempts have been made to compare reactivities of dissolved and surface-bound metal species (Wehrli, 1990; Wehrli et al., 1990). To compare the catalytic reactivity of dissolved and surface-bound metals, any unusual or unique characteristic of the mineral/water interface must be investigated. The high Lewis and Brønsted acidity of unoccupied coordinative sites is responsible for the well-known hydrolytic reactivity of dehydrated and partially dehydrated mineral surfaces (Theng, 1982; Voudrias and Reinhard, 1986). Although the catalysis by surface-bound metals is influenced by hydration, dramatic effects of solid surfaces on hydrolysis rates in aqueous suspensions have been demonstrated (Sanchez-Camazano and Sanchez-Martin, 1983).

The catalysis by surface-bound metals is observed when all participating reactants are adsorbed to a significant extent and when rate constants for the reactions at the mineral–water surface are comparable to or exceed rate constants for the reaction in homogeneous solution. Although adsorption phenomena have accounted for catalysis, relatively little is known about the conformation and stoichiometry of adsorbed species. This hampers our understanding of surface catalysis on a fundamental level. However, based on the existing literature, two generalities can be made: (1) auxiliary donor groups that facilitate metal catalysis by metal ions in solution should also facilitate surface catalysis and (2) phenomena of only secondary importance in reactions of dissolved complexes, for example, electrostatic and hydrophobic interactions may play a much greater role in surface catalysis (Stone and Torrents, 1995). The nature and potential significance of surface catalysis are summarized later.

The hydrolysis of phenyl picolinate (PHP) is catalyzed by both surface-bound and homogeneous solution metal ions (type 1 catalysis; Fife and Przystas, 1985; Torrents and Stone, 1991). Appropriate metal ions chelate the heterocyclic N and carbonyl O of PHP and increase the partial positive charge at the carbonyl C, thus facilitating nucleophilic attack and increasing its susceptibility to hydrolysis. Suspensions containing FeOOH or TiO_2 dramatically accelerate PHP hydrolysis rate, while in particle-free solution and suspensions containing Al_2O_3 or SiO_2, hydrolysis is negligible (Figure 18.7). Similar results are obtained with methyl picolinate (MEP; Stone and Torrents, 1995). Catalysis arises from reaction at the oxide surface and not from release of soluble metals, since removal of particles by filtration causes an immediate halt to any catalytic activity.

The susceptibility of hydrolyzable compounds to metal catalysis depends on the nature of the auxiliary donor group. The pyridyl N of PHP and MEP encourages chelate formation with Ti(IV) and Fe(III) in preference to less polarizable Al. Therefore, TiO_2 and FeOOH are effective hydrolysis catalysts and Al_2O_3 is not. In contrast, O donor groups, such as the phenolic group in phenyl salicylate and the O heteroatom of methyl furanoate, are harder and thus more favorable to Al chelate formation (Stone and Torrents, 1995). Hydrolysis of PHP in the presence of TiO_2 is virtually pH independent and in the presence of FeOOH exhibits only a slight pH dependence. In particle-free solution, PHP exhibits classic base-catalyzed hydrolysis behavior; the reaction rate of the hydrolysis increases by an order of magnitude for every unit increase in pH. Activation of the ester linkage through chelate formation with a surface-bound metal ion is apparently strong enough to react with the weak nucleophile H_2O, which dominates over the pH-dependent reaction with OH^-.

Positively charged surfaces such as Al_2O_3 (below pH 8.6) and TiO_2 (below pH 6.4) accelerate the hydrolysis of monophenyl terephthalate (MPT) by an order of magnitude or more (Stone and Torrents, 1995). Hydrolysis of MPT catalyzed by Al_2O_3
FIGURE 18.7 Effect of various metal oxides on the loss of phenyl picolinate (PHP) from solution via hydrolysis. All suspensions contained $10\,g\,L^{-1}$ oxide, $1.0\,m\,mol\,L^{-1}$ acetate buffer (pH 5.0), and 50 mM NaCl. (Reprinted with permission from Torrents, A., and A.T. Stone. 1991. Hydrolysis of phenyl picolinate at the mineral/water interface. Environ. Sci. Technol. 25:143–149. Copyright 1991 American Chemical Society.)

and TiO_2 exhibits elements of both type 3 and type 6 catalyses. Positive oxide surfaces serve as the template to accumulate both anionic reactants, OH^- and MPT ions, increasing their encounter frequency. Type 6 catalysis (electrostatic interactions favoring encounter between like-charge species) is more important for surface chemical reactions than for solution reactions due to the additive electrostatic effect arising from neighboring charged groups. Type 3 catalysis (simultaneous attachment of substrate and nucleophile) is also typical of surface chemical reactions.

Many pesticides are susceptible to surface-catalyzed hydrolysis (Torrents, 1992). For example, catalysis of chlorpyrifos hydrolysis by TiO_2, FeOOH, and Al_2O_3 apparently involves chelate formation between the surface-bound metal ion, the thionate S, and pyridinyl N.

A surface-catalyzed reaction following type 4 catalysis has been postulated for the degradation of the fungicide oxycarboxin stored in borosilicate glass (Stanton, 1987). Because of low hydroxide ion concentration in neutral and acidic pH, hydrolytic ring cleavage is not observed in the absence of a catalyst. The glass exerts its catalytic effect by providing sufficiently strong nucleophiles (surface-bound OH^- and O_2^{2-}) for attacking the oxathiin ring. Quartz and aluminosilicate surfaces present in soils and associated environments could also catalyze oxycarboxin hydrolysis. It has been reported that metal oxides catalyze the hydrolysis of *p*-nitrophenyl acetate by this mechanism (Hoffmann, 1990). However, in surface-catalyzed

hydrolysis reactions, the nature and relative significance of type 4 catalysis are poorly understood and, thus, merit closer attention.

Among the clay minerals, montmorillonite, beidellite, illite, and vermiculite, only montmorillonite is able to enhance the hydrolysis of the carbamate pesticides, carbosulfan, and aldicarb, probably due to its stronger surface acidity and chelating ability compared to the other clay minerals (Wei et al., 2001). Suspensions of sea sand, TiO_2, α-Fe_2O_3, α-FeO(OH), laponite (smectite clay), and SiO_2 are able to catalyze the hydrolysis of the cyclodiene pesticide, endosulfan to the less toxic endosulfan diol (Walse et al., 2002). The rates of endosulfan hydrolysis over the different surfaces correspond to their tritium-exchange site-density and suggest a mechanism involving surface coordination prior to nucleophilic attack (Walse et al., 2002).

Birnessite is able to catalyze the hydrolysis of the herbicide atrazine (2-chloro-4-(ethylamino)-6-(isopropylamino)-1,3,5-triazine) by acting as a Lewis acid activator and a source of metal-bound hydroxide as a nucleophile (Figure 18.8) (Shin and Cheney, 2004, 2005). Furthermore, birnessite is also able to catalyze the N-dealkylation of atrazine via a nonoxidative mechanism involving proton transfer to Mn(IV)-stabilized oxo and imido bonds (Wang et al., 1999; Shin and Cheney, 2005).

Recently, it has been shown that dissolved HAs are able to catalyze the abiotic hydrolysis of phenylurea herbicides by acting as bifunctional buffers, similar to HCO_3^-/CO_3^{2-} or $H_2PO_4^-/HPO_4^{2-}$. The hydrolysis reaction rate increases with the carboxyl group
FIGURE 18.8 Hypothesized hydroxyatrazine formation pathway from the reaction of atrazine with birnessite (δ-MnO_2) at pH 4.3 and 20°C. (From Shin, J.Y., and M.A. Cheney. 2005. Abiotic dealkylation and hydrolysis of atrazine by birnessite. Environ. Toxicol. Chem. 24:1353–1360. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.)

content of the HAs, indicating that the carboxyl groups are responsible for the catalysis (Salvestrini et al., 2008).

18.3.5 Reductive Transformation of Organic Compounds

In anoxic groundwater and surficial water, biogeochemical processes provide a variety of potential reductants for abiotic contaminant transformation. Persistent xenobiotics, such as polyhalogenated alkanes and alkenes, aromatic nitro and azo compounds, may be transformed to reaction products that can be further microbially degraded or to products that can be more toxic than the parent compounds (Hofstetter et al., 2006).

18.3.5.1 Ferrous Iron as Catalyst

Soluble Fe(II) is an important reductant in anaerobic aqueous environments; however, its availability is limited in neutral and alkaline pH ranges by the precipitation of FeS, $Fe_3(PO_4)_2$, $FeCO_3$, and other Fe(II)-rich minerals (Charlet et al., 1998). Ferrous iron present within or sorbed on iron oxide mineral particles is highly reactive even at high pH conditions (Charlet et al., 1998). Reduction of nitrite ions to N_2O by Fe(II) sorbed on lepidocrocite at a pH range of 6.0–8.5 was demonstrated by Sorensen and Thorling (1991). Above pH 5.5, Fe^{2+} starts to be adsorbed onto particles, and this adsorption is completed on most mineral phases around pH 7.5, that is, before the onset of precipitation. Above pH 6.5, a significant part of sorbed Fe(II) is present as a highly reactive hydroxylated surface complex, =Fe(III)–O–Fe(II)–OH (Charlet et al., 1998). This hydrolyzed surface species is a very effective reductant toward many persistent xenobiotics, such as 4-chloronitrobenzene (Charlet et al., 1998).

Mossbauer spectra of Fe(II) adsorbed to rutile (TiO_2) and aluminum oxide (Al_2O_3) show only Fe(II) species, whereas spectra of Fe(II) reacted with the iron oxides, goethite, hematite, and ferrihydrite demonstrate electron transfer between the adsorbed Fe(II) and the underlying iron(III) oxide (Williams and Scherer, 2004). The electron transfer reactions that occur during the reduction of nitrobenzene induce growth of an Fe(III) layer on the oxide surface that is similar to the bulk oxide (Williams and Scherer, 2004). Similarly, it has been shown that the reductive degradation of 4-chloronitrobenzene and trichloronitromethane in the presence of Fe(II) and goethite results in the growth of goethite in the c-direction; however, the newly formed goethite is progressively less reactive than the original goethite (Chun et al., 2006).

Ferrous iron in the presence of goethite can catalyze the abiotic reductive degradation of the widely used dinitroaniline herbicides (trifluralin, pendimethalin, nitralin, and isopropalin) at neutral solution pH (Klupinski and Chin, 2003; Wang and Arnold, 2003). Increasing the solution pH results in increased rate constants due to the increase in Fe(II) sorbed and creation of highly reactive species on the surface of the goethite (Figure 18.9) (Wang and Arnold, 2003). Nitrobenzenes and N-hydroxylanilines are reaction intermediates of the reduction of nitroaromatics. Nitrobenzenes, the first intermediates,
FIGURE 18.9 Role of pH on the sorbed Fe(II) (○) and observed pseudo-first-order rate constants (●) for the reduction of trifluralin with $1\,mmol\,L^{-1}$ Fe(II) in a suspension of $7.2\,m^2\,L^{-1}$ ($0.65\,mg\,mL^{-1}$) goethite. The k_{obs} value (■) at pH 7.8 was extrapolated from a regression of log k_{obs} versus pH. (Reprinted from Wang, S., and W.A. Arnold. 2003. Abiotic reduction of dinitroaniline herbicides. Water Res. 37:4191–4201. Copyright 2003, With permission from Elsevier.)

are readily reduced by soluble Fe(II) and Fe(II)-treated goethite suspensions, especially if there are electron-withdrawing substituents in the *para* position (Colon et al., 2006b). However, N-hydroxylanilines, the second intermediates, are only reduced in the presence of Fe(II)-treated goethite suspensions, and in contrast to nitrobenzenes, electron-withdrawing substituents in the *para* position decrease the rate of reduction (Colon et al., 2006b). The rate of reduction of p-cyano-N-hydroxylaniline showed a linear relationship against the concentration of mineral surface-associated Fe(II) in hematite, goethite, and lepidocrocite suspensions (Colon et al., 2006b). The reactivity of mineral surface-associated Fe(II) toward the reduction of p-cyano-nitrobenzene decreases in the order hematite > goethite > lepidocrocite > ferrihydrite, and interestingly, the surface density of surface-bound Fe(II) does not play a major role in determining the observed reactivity trend (Colon et al., 2006a).

Ferrous iron in the presence of goethite and magnetite abiotically catalyzes the degradation of trichloronitromethane via reduction, while trichloroacetonitrile, 1,1,1-trichloropropanone, and trichloroacetaldyde hydrate are transformed via both hydrolysis and reduction reactions (Chun et al., 2005). The Fe(II) bound to the iron minerals has a greater reactivity than either aqueous Fe(II) or structural Fe(II) present in magnetite (Chun et al., 2005). Ferrous iron bound to magnetite is an effective catalyst for the degradation of the high-energy explosive RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine), ultimately breaking it down into NH_4^+, N_2O, and formaldehyde (Gregory et al., 2004).

Ferrous iron sorbed on the surface of goethite is able to catalyze the abiotic reductive dehalogenation of carbon tetrachloride (CCl_4) to form the even more toxic compound, chloroform ($CHCl_3$) (Amonette et al., 2000). The reductive dehalogenation of carbon tetrachloride did not occur in the presence of soluble Fe(II) without goethite (Amonette et al., 2000). Reduction of CCl_4 by surface-associated Fe(II) on goethite occurs in a single

electron transfer reaction and results in the cleavage of one C–Cl bond and the generation of unstable trichloromethyl radicals, as shown below (Elsner et al., 2004a):

$$CCl_4 \xrightarrow[{-1\ Cl^-}]{+1\ e^-} {}^{\bullet}CCl_3 \begin{array}{l} \xrightarrow{O_2} \longrightarrow \longrightarrow (O{=}CCl_2),\ CO_2 \\ \xrightarrow{R\text{-}S^-} \text{Sulfur adducts} \\ \xrightarrow{e^-} {:}CCl_3^- \\ \xrightarrow{R\text{-}H} CHCl_3 \end{array} \qquad (18.11)$$
The presence of oxygen and sulfur species can thus lead to completely dehalogenated reaction products in radical reactions. However, the presence of H radical donors, such as trace amounts of natural organic matter, promotes the formation of toxic chloroform (Elsner et al., 2004a). Ferrous iron bound to the surface of iron oxides (goethite, hematite, lepidocrocite, and magnetite) is capable of reducing a variety of other polyhalogenated methanes under aquifer conditions, and the pseudo-first-order reaction rate constants, k_{obs}, of the polyhalogenated methanes increased in the order $CHBrCl_2 < CHBr_2Cl < CHBr_3 < CCl_4 < CFBr_3 < CBrCl_3 < CBr_2Cl_2$ (Pecher et al., 2002).

Reactive Fe(II) does form not only on the surface of oxides but also on the surfaces of other iron minerals such as iron sulfide (FeS), pyrite (FeS_2), and siderite ($FeCO_3$) (Elsner et al., 2004b). Elsner et al. (2004b) compared the 4-chloronitrobenzene, 4-chlorophenyl hydroxylamine, and hexachloroethane-reducing reactivity of Fe(II) aqueous suspensions in the presence of siderite, hematite, lepidocrocite, goethite, magnetite, sulfate green rust, pyrite, and mackinawite. The surface area-normalized reaction rates generally increase in the order Fe(II) + siderite < Fe(II) + iron oxides < Fe(II) + iron sulfides (Elsner et al., 2004b).

Ferrous iron-bearing minerals are also important environmental abiotic reductants. Magnetite, pyrite, and green rust are able to catalyze the abiotic reductive dechlorination of chlorinated ethylenes (Kriegman-King and Reinhard, 1994; Butler and Hayes, 1998; Lee and Batchelor, 2002a, 2002b). Surface area-normalized pseudo-first-order initial rate constants for the reduction of chlorinated ethylenes (tetrachloroethylene, trichloroethylene, *cis*-dichloroethylene, and vinyl chloride) by green rust were found to be 3.4–8.2 times greater than those by pyrite (Lee and Batchelor, 2002b), and the rate constants by pyrite were found to be 23.5–40.3 times greater than those by magnetite (Lee and Batchelor, 2002a).

In clay minerals, Fe(II) may be present as (1) structural Fe(II), (2) Fe(II) complexed by surface hydroxyl groups, and (3) Fe(II) bound by ion exchange. Hofstetter et al. (2003) investigated the accessibility and reactivity of these three types of Fe(II) species in suspensions of ferrous iron-bearing nontronite or iron-free hectorite. They found that both structural Fe(II) and Fe(II) complexed by surface hydroxyl groups of nontronite reduced the nitroaromatic compounds to anilines. Fe(II) bound by ion exchange did not contribute to the observed reduction of the nitroaromatic compounds. The abiotic reductive reactivity of

biotite, vermiculite, and montmorillonite on chlorinated ethylenes (tetrachloroethylene, trichloroethylene, *cis*-dichloroethylene, and vinyl chloride) with or without the addition of Fe(II) was investigated by Lee and Batchelor (2004). Biotite had the greatest rate constant among the phyllosilicates, both with and without Fe(II) addition (Figure 18.10), which is attributed to the higher content of Fe(II) sites on biotite. The Fe(II) content of biotite is 8 and 97.5 times higher than that of vermiculite and montmorillonite, respectively (Lee and Batchelor, 2003). The addition of Fe(II) to the mineral suspensions increased the rate constants of the dechlorination reactions, which is attributed to the regeneration of active sites on the phyllosilicates resulting from redox reaction with Fe(II) or due to the reactivity of Fe(II) that binds to the phyllosilicate surfaces (Lee and Batchelor, 2004).

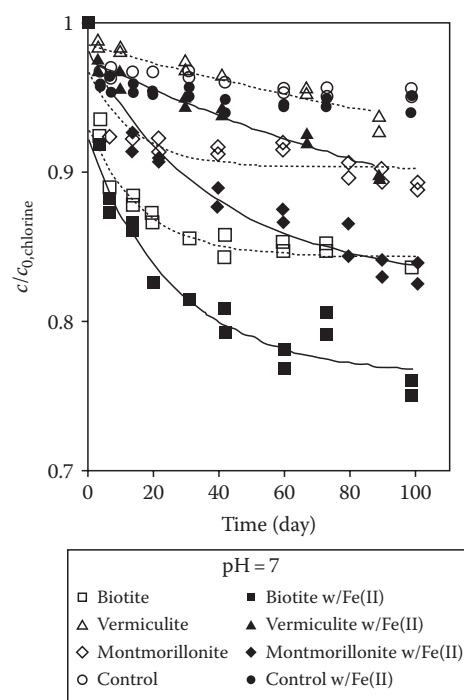
Ferruginous smectite, chemically reduced with dithionite is able to reduce and dechlorinate trichloroacetonitrile and chloropicrin (Cervini-Silva et al., 2001). Similarly, chemically reduced montmorillonite and ferruginous smectite are able to catalyze the abiotic reduction of nitrobenzene to aniline, and as much as 40% of the structural Fe(II) in the reduced smectite was oxidized to Fe(III) during the reaction (Yan and Bailey, 2001). Hofstetter et al. (2006) investigated the reactivity of Fe(II) species in suspensions of chemically reduced montmorillonite, with a low structural iron content, and reduced iron-rich nontronite


FIGURE 18.10 Reductive dechlorination of chlorinated ethylenes (0.19 mM) in iron-bearing phyllosilicate suspensions (0.085 g g^{-1}) with and without Fe(II) addition (4.28 mM). (Reprinted from Lee, W.J., and B. Batchelor. 2004. Abiotic reductive dechlorination of chlorinated ethylenes by iron-bearing phyllosilicates. Chemosphere 56:999–1009. Copyright 2004, with permission from Elsevier.) C_0 and C stand for the concentration (mM) of the organic chlorine compound at time 0 and the sampling time.

using acetylnitrobenzene compounds. Their results indicate that Fe(II) bound in the octahedral sheet of reduced smectites is the predominant reductant, and that electron transfer presumably occurs via basal siloxane planes. Nonreactive electron donor–acceptor complexation of the nitroaromatic compounds occurred at the basal smectite surfaces of the reduced montmorillonite but was not observed in suspensions of reduced iron-rich nontronite.

Reduced aquifer sediments from the perched Pantex aquifer (Amarillo, TX) were found to efficiently, abiotically degrade the explosives RDX, HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine), and TNT (Boparai et al., 2008). When Fe(II) was partially removed from the reduced sediments by washing (citrate-bicarbonate buffer), RDX degradation was suppressed, but the addition of Fe(II) restored the degradation efficiency of the sediment (Boparai et al., 2008).

18.3.5.2 Natural Organic Matter as Catalyst and Redox Mediator/Inhibitor

Humus plays a significant role in the anaerobic degradation of xenobiotics by shuttling electrons. Humic functional groups, in particular quinones, can act as redox mediators and electron donors for accelerating abiotic reductive transformation processes (Field et al., 2000; Doong and Chiang, 2005; Fimmen et al., 2007; Ratasuk and Nanny, 2007). Electrochemically reduced soil and aquatic HAs are able to reduce hexachloroethane at appreciable rates, which indicates that HA could play an important role in the reductive transformation of xenobiotics in anoxic environments (Kappler and Haderlein, 2003).

Natural organic matter can act as an electron transfer mediator in the presence of a bulk electron donor such a Fe(II) or HS⁻ and thus significantly enhances the rate of reduction of halogenated hydrocarbons, such as carbon tetrachloride or bromoform (Curtis and Reinhard, 1994) or substituted nitrobenzenes (Dunnivant et al., 1992). Strathmann and Stone (2002) demonstrated that natural organic matter from the Great Dismal Swamp facilitates oxime carbamate pesticide reduction by Fe(II) in the same manner as individual organic ligands, carboxylate, and aminocarboxylate.

Complexation of Fe(II) by catechol and organothiol ligands, which are similar to the functional groups found in natural humic substances, leads to the formation of highly reactive aqueous species that are capable of reducing substituted nitroaromatic compounds (Naka et al., 2006, 2008). The nitroaromatic compounds are not reduced in Fe(II)-only or ligand-only solutions (Naka et al., 2006, 2008). The high reactivity of these Fe(II)–organic ligand complexes is attributed to a lowering of standard one-electron reduction potential of the Fe(III)/Fe(II) redox couple on complexation by the ligands. The organothiol ligands are also able to re-reduce the Fe(III) that forms when Fe(II) complexes are oxidized by reactions with the nitroaromatic compounds (Naka et al., 2008). Ferrous iron–catechol and ferrous iron–organothiol complexes are also able to completely reductively degrade the explosive RDX (Kim and Strathmann, 2007) and to catalyze the reductive degradation of polyhalogenated alkanes

(Bussan and Strathmann, 2007). Iron(II)–tiron complexes are able to quantitatively reduce trichloroethane to acetaldehyde, a product previously only reported for reactions with Cr(II), but not with Fe-based reductants (Bussan and Strathmann, 2007).

The explosive RDX is rapidly reductively degraded in the presence of black carbon (BC) and sulfide to low-molecular-weight ring-cleavage products (Kemper et al., 2008). RDX was not degraded in the presence of BC-only or sulfide-only suspensions. Due to the heterogeneous nature of BC, it remains unclear whether the quinone material in the BC or the ability of BC to sorb the hydrophobic RDX facilitated the reductive degradation (Kemper et al., 2008).

On the other hand, natural organic matter can decrease the reductive potential of Fe(II) by competing for reactive sites on Fe(II)-mineral surfaces. Hakala et al. (2007) found that dissolved organic matter only enhances the reductive capacity of Fe(II) toward nitroaromatic compounds in the absence of iron oxide colloids. Colon et al. (2008) found that Suwannee River HA decreases the reduction capacity of Fe(II)-treated goethite toward nitrobenzene, by complexing the surface-associated Fe(II) species or hindering access of nitrobenzenes to the Fe(II) sites.

18.3.6 Genotoxicity and Bioavailability of Xenobiotics as Influenced by Mineral Catalysis

Much is known about the toxicity of xenobiotic parent compounds, whereas, relatively little work has been carried out on investigating the toxicity of the degradation products of xenobiotics (Sinclair and Boxall, 2003). In some cases, the transformation products of xenobiotics, such as commonly used pesticides and herbicides, can be even more toxic than the parent compound (Osano et al., 2002; Sinclair and Boxall, 2003). To date, very little research has been carried out on investigating the bioavailability and toxicity of xenobiotics after reaction with abiotic catalysts, such as metal oxides or clay minerals.

The oxidative coupling of the polycyclic aromatic hydrocarbon, phenanthrene, with catechol as catalyzed by birnessite significantly reduces the bioavailability of phenanthrene to microorganisms (Russo et al., 2005). The oxidative coupling of phenol induced by birnessite or soil significantly decreases the toxicity of the compound as determined with a Microtox System (Jung et al., 2008b).

The pesticides, oxamyl (carbamate family) and alachlor (chloroacetanilide family), reacted with reduced nontronite clay (ferruginous smectite) show a significant decrease in their overall mammalian cell cytotoxic (toxicity to cells) potential, whereas the pesticide 2,4-D (phenoxy family) shows no difference in toxicity after treatment with the reduced clay (Sorensen et al., 2004). The pesticide, dicamba (benzoic acid family), reacted with reduced nontronite clay actually generates products, which are more cytotoxic than the parent compound (Sorensen et al., 2004). Oxidized nontronite had no effect on the cytotoxicity of any of the aforementioned pesticides, which indicates reduced

Fe in smectites plays an important role in altering the cytotoxicity of pesticides and should thus be taken into account in pesticide management programs (Sorensen et al., 2004).

The genotoxic potency (potential damaging effect on DNA) of most pesticides in mammalian cells is unknown, let alone their abiotic transformation products. Sorensen et al. (2005) were the first group to investigate the effect of reduced ferruginous smectite on the genotoxicity of the pesticides 2,4-D, dicamba and oxamyl. Neither 2,4-D alone nor its transformation products after reaction with the reduced clay were found to be genotoxic. The genotoxicity of oxamyl actually decreased after reaction with the reduced clay. Dicamba alone was not genotoxic but became genotoxic after reaction with the reduced clay.

18.4 Abiotic Catalysis in the Transformation of Metals, Metalloids, and Other Inorganics

18.4.1 Transformation of Metals and Metalloids

18.4.1.1 Arsenic

Arsenic bioavailability and toxicology depend on its chemical state (Huang and Fujii, 1996) with As(III) (arsenite) being much more toxic than As(V) (arsenate). Manganese(IV) oxides, such as birnessite (Table 18.5), are very effective oxidants of As(III) (Oscarson et al., 1981a, 1981c, 1983b; Feng et al., 2006b). In the control experiment, no detectable As(III) is oxidized in the absence of Mn(IV) oxide (Table 18.5). Arsenic(III) oxidation by birnessite proceeds through two single electron transfer steps with the formation of Mn(III) as intermediate (MnOOH), as follows (Nesbitt et al., 1998; Tournassat et al., 2002):

$$2MnO_2 + H_3AsO_3 = 2MnOOH + H_3AsO_4, \qquad (18.12)$$

$$2MnOOH + H_3AsO_3 = 2MnO + H_3AsO_4 + H_2O. \qquad (18.13)$$

Poorly crystalline Fe(III) oxyhydroxides (Devitre et al., 1991; Nicholas et al., 2003; Jang and Dempsey, 2008) and the surfaces

FIGURE 18.11 Oxidation of As(III) to As(V) and the sorption of As by lake sediments as a function of time. (a) Concentration of As(III) in solution, (b) concentration of As(V) in solution, and (c) As(III)/As(III) + As(V). Ten μg mL^{-1} of As(III) were added initially. During the reaction period, the pH of the As-sediment suspension ranged from 8.0 to 8.2 for the Buffalo Pound sediment and from 7.3 to 7.6 for the other four sediments. (Reprinted from Oscarson, D.W., P.M. Huang, and W.K. Liaw. 1980. The oxidation of arsenite by aquatic sediments. J. Environ. Qual. 9:700–703. With permission of the American Society of Agronomy.)

TABLE 18.5 Oxidation of As(III) and Sorption of As by Mn(IV) Oxide (in μg mL^{-1} in Solution)

As(III) or As(V) Added (μg mL^{-1})	As(III)	As(V)	Mn	Final pH
100 As(III)	ND[a]	83.5 ± 1.4[b]	0.41 ± 0.12	7.1
300 As(III)	63.2 ± 7.0	186 ± 5	8.08 ± 0.36	7.1
500 As(III)	213 ± 4	205 ± 1	6.06 ± 0.60	7.3
1000 As(III)	665 ± 5	216 ± 4	4.16 ± 0.86	7.5
300 As(V)	ND	298 ± 1	0.06 ± 0.02	7.5

of the clay minerals illite and kaolinite (Manning and Goldberg, 1997) are also able to catalyze the oxidation of As(III).

Although As(V) is a thermodynamically stable species in oxygenated water at common pH values (Penrose, 1974), the kinetics of oxidation of As(III) with O$_2$ is very slow at near-neutral pH values (Kolthoff, 1921). Lake sediments from Saskatchewan, Canada, can oxidize As(III) (700 μg As) to As(V) within 48 h (Figure 18.11). The oxidation of As(III) is not detectable within 72 h in the absence of sediment. The oxidation of As(III) to As(V) is not affected by flushing N$_2$ or air through the sediment suspensions, nor does the addition of HgCl$_2$ to the system eliminate the conversion of As(III) to As(V). This indicates that the oxidation of As(III) to As(V) is an abiotic process.

When the lake sediments are treated with hydroxylamine hydrochloride or sodium acetate, which are effective extractants for Mn, the oxidation of As(III) to As(V) by the treated sediments is greatly decreased relative to the untreated sediments

(Oscarson et al., 1981c). Hydroxylamine hydrochloride treatment also removes Fe oxide; however, the evidence obtained from colorimetry and x-ray photoelectron spectroscopy shows that a redox reaction between Fe oxide and As(III) does not occur within 72 h, indicating that the redox reaction between As(III) and Fe(III) is kinetically slow (Oscarson et al., 1981a). This supports the evidence that Mn oxide is the primary component responsible for catalyzing the conversion of As(III) to As(V). The rate constant increases with increasing temperature from 278 to 298 K; the heat of activation for the process varies from 13.8 to 35.6 kJ mol⁻¹, indicating that the depletion of As(III) is predominantly a diffusion-controlled process (Oscarson et al., 1981b). Other recent studies have also suggested that Mn oxides are largely responsible for the oxidation of As(III) in aquifer sediments from Maine, USA (Amirbahman et al., 2006) and Dhaka, Bangladesh (Stollenwerk et al., 2007).

The ability of Mn oxides to deplete As(III) from solution (oxidation plus sorption) varies with their crystallinity and specific surface (Oscarson et al., 1983b). The depletion of As(III) by Mn oxides follows the first-order kinetics. Pyrolusite is highly ordered and has a low specific surface; conversely, birnessite and cryptomelane are poorly crystalline and have relatively high specific surfaces (Table 18.6). Because birnessite and cryptomelane have relatively high specific surface areas due to their porous nature (Huang, 1991b), their rate constants for the depletion of As(III) are much higher than those for pyrolusite (Table 18.6). On the other hand, the rate constants for the depletion of As(III) by birnessite are significantly greater than those for cryptomelane, despite its higher specific surface. Birnessite has a greater negative charge density than cryptomelane at pH 7 (McKenzie, 1981). Because As(V) is also negatively charged at pH 7, the repulsive interaction energy would be greater between birnessite than cryptomelane and As(V), which is why birnessite does not sorb a detectable amount of As(V) relative to cryptomelane (Oscarson et al., 1983b). Differences in the point of zero charge (p.z.c.) of birnessite and cryptomelane and their ability to sorb As(V) explain the greater As(III) depletion by birnessite than by cryptomelane even though cryptomelane has the greater surface area. Little As(V) is sorbed from solution by birnessite upon oxidation of As(III), and less total As is sorbed by birnessite than by cryptomelane; the electron-accepting sites on the surface of birnessite are, thus, blocked to a lesser extent than those on the surface

of cryptomelane. Consequently, the rate of depletion of As(III) from solution is greater for birnessite than for cryptomelane.

The structure and composition of Mn oxides, as well as the solution pH, ionic strength, and presence of organic ligands all affect the rate of As(III) oxidation by Mn oxides. Tunnel-structured cryptomelane has the strongest As(III) oxidation ability (842.2 mmol kg⁻¹), compared with layered–structured birnessite (480.4 mmol kg⁻¹), and Mn(II/III)-bearing hausmannite (117.9 mmol kg⁻¹) (Feng et al., 2006b). Increasing the reaction system pH from 3.0 to 6.5 results in a significant increase in the rate of oxidation of As(III) by the three Mn oxides, whereas increasing the ionic strength results in a decrease in the oxidation of As(III) by birnessite and cryptomelane, while hausmannite is unaffected (Feng et al., 2006b). The presence of tartaric acid at a concentration below 4 mol L⁻¹ promotes oxidation of As(III) by birnessite, cryptomelane, and hausmannite, whereas it decreases As(III) oxidation by cryptomelane and hausmannite when the concentration is increased above 4 mol L⁻¹ (Feng et al., 2006b). The oxidation of As(III) by the Mn oxyhydroxide, manganite [MnO(OH)], occurs on the time scale of hours. The presence of competing anions such as phosphate decreases the oxidation rate of As(III) to As(V) by manganite (Chiu and Hering, 2000). The presence of a divalent cation, Zn^{2+}, significantly suppresses the oxidation of As(III) by birnessite, and this suppression is more pronounced when the Zn^{2+} is presorbed on the birnessite (Power et al., 2005).

The surfaces of many soil Mn oxides are coated with various chemical species (McKenzie, 1989). The rate constants for the depletion (oxidation plus sorption) of As(III) are generally substantially smaller for the Mn oxides with higher levels of coatings of Fe and Al oxides and $CaCO_3$ than those for the untreated MnO_2 or MnO_2 with lower levels of coatings (Oscarson et al., 1983a). HA coatings on natural Mn nodules also significantly reduce the As(III) depletion capacity of the nodules (Chen et al., 2006). The electron-accepting sites on MnO_2 are partially masked by the oxides, $CaCO_3$, and organic matter. There is evidence that shows that Fe(III) and Al oxides and $CaCO_3$ do not oxidize As(III) to As(V) (Oscarson et al., 1981a, 1983a), and thus, the oxidation of As(III) to As(V) on the coated MnO_2 is solely attributed to MnO_2 in this case.

However, some studies have shown that Fe oxides and oxyhydroxides can catalyze the oxidation of As(III) to As(IV). Devitre et al. (1991) showed that As(III) is rapidly oxidized by diagenetic

TABLE 18.6 Specific Surface and Point of Zero Charge (p.z.c.) of the Mn Dioxides and Rate Constants and Energies of Activation for the Depletion of As(III) by the Mn Dioxides

Mineral	Specific Surface (m² g⁻¹)	p.z.c.	Rate Constant × 10⁻³ (h⁻¹)			Energies of Activation (kJ mol⁻¹)
			278 K	298 K	318 K

amorphous Fe(III) oxyhydroxides. The rapid oxidation of As(III) is observed on the Fe oxyhydroxide, ferrihydrite, in the presence of hydrogen peroxide (Nicholas et al., 2003). Jang and Dempsey (2008) found that the oxidation of As(III) by Fe oxyhydroxides is significant only in the presence of As(V). Magnetite (Fe_3O_4) is able to catalyze the oxidation of As(III), which is attributed to the presence of structural Fe(III) and possible Mn impurities in the magnetite (Su and Puls, 2008).

The oxidation of As(III) by the Mn oxides, birnessite, todorokite, and hausmannite, increases significantly in the presence of the Fe(III) oxide, goethite (Feng et al., 2006a). Goethite promotes As(III) oxidation on the Mn oxide minerals by adsorption of the As(V) produced during the reaction, thus decreasing the As(V) concentration in solution. Therefore, the combined effects of the Mn and Fe oxide minerals can lead to the rapid oxidation and immobilization of As in soils (Deschamps et al., 2003; Feng et al., 2006a).

The conversion of As(III) to As(V) by uncoated and coated Mn oxides has important implications for the transport, fate, and toxicity of As in terrestrial and associated environments. In some environments that have been contaminated with As(III), the addition of reactive Mn oxides may alleviate the toxicity of As(III) through their catalytic reactions.

18.4.1.2 Selenium

Selenium is an essential trace element in the human and animal nutrition; however, there is a very narrow optimal concentration range between deficiency and toxicity (selenosis). The mobility and availability of Se are largely controlled by its redox state, which affects its sorption to mineral and organic matter surfaces (Masscheleyn et al., 1990; Charlet et al., 2007). Selenium(VI) is the stable valence state in oxic environments and exists as the selenate (SeO_4^{2-}) oxyanion. Selenium(IV) is the stable valence state under mildly reducing or anoxic conditions and exists as the selenite (SeO_3^{2-}) oxyanion. Selenate is weakly sorbed by minerals and is more soluble and bioavailable than selenite, which binds strongly to the surfaces of metal oxides by inner-sphere complexes. In reducing sediments, Se(VI) and Se(IV) can be reduced to Se(0) and other reduced species (oxidation states of −1 and −2), such as Se-pyrite or ferroselite. The formation of elemental and pyritic Se is regarded as an important mechanism for controlling the availability of Se in the environment (Belzile et al., 2000). The reduction of Se(VI) and Se(IV) may be facilitated by sorption of these species on the surfaces of Fe–Mn oxyhydroxides or Fe(II)-bearing minerals or by the involvement of HS^-, pyrite, and organic matter (Myneni et al., 1997; Belzile et al., 2000; Bruggeman et al., 2005; Charlet et al., 2007; Scheinost and Charlet, 2008). Previously it was thought that these reactions are principally mediated by microorganisms (Myneni et al., 1997).

The abiotic reduction of Se(VI) and Se(IV) to Se(0) can be catalyzed by Fe(II) either sorbed on the surfaces of clays or structurally present in Fe-bearing minerals. Green rust, an Fe(II/III) oxide commonly present in reduced sediments and soils, is able to reduce Se(VI) to Se(IV) and Se(0) by adsorption
FIGURE 18.12 In situ XANES spectra of Se(VI) reaction with green rust as a function of sorption mechanisms (coprecipitation [Cop.] and adsorption [Ads]). The XANES spectra of Se models in different oxidation states are shown for comparison. The vertical line in the center shows the position of Se(VI). (Reprinted from Myneni, S.C.B., T.K. Tokunaga, and G.E. Brown. 1997. Abiotic selenium redox transformations in the presence of Fe(II,III) oxides. Science 278:1106–1109. With permission of the American Association for the Advancement of Science.)

and coprecipitation mechanisms (Figure 18.12) (Myneni et al., 1997). The reaction proceeds as follows; magnetite is produced during the oxidation of the green rust:

$$HSeO_4^- + 4Fe_4^{II}Fe_2^{III}(OH)_{12}SO_4\,3H_2O$$

$$\leftrightarrow HSe^- + 8Fe_3O_4 + 4SO_4^{2-} + 8H^+ + 32H_2O. \qquad (18.14)$$
Similarly, zero-valent iron reacted with Se(VI) catalyzes the formation of Se(0) and produces a green rust layer on the exposed surfaces of the iron(0) (Scheidegger et al., 2003).

The reduction of selenite [Se(IV)] to solid Se(0) can be catalyzed by Fe(II)-bearing mineral, pyrite (FeS_2), via the process of adsorption on the surface of pyrite (Bruggeman et al., 2005; Breynaert et al., 2008). The presence of illite-rich Boom clay sediments (Belgium) and natural humic substances decreases the rate of selenite reduction by pyrite due to the competitive adsorption (Bruggeman et al., 2005). Troilite (FeS) is also able to catalyze the reduction of selenite, however, through a different mechanism that involves reduction by dissolved sulfide and the formation of Se(0) as an intermediate (Breynaert et al., 2008). The Se(0) is then further reduced to $FeSe_x$ species, which precipitate on the surface of the troilite. Nanoparticulate Fe(II)-bearing

minerals mackinawite [(Fe, Ni)$_{1+x}$S$_x$] and magnetite (Fe$_3$O$_4$), and micrometer-sized siderite (FeCO$_3$) are able to rapidly reduce selenite (Scheinost and Charlet, 2008). Mackinawite reduces selenite to Se(0) at pH 6.3 and FeSe at pH 4, whereas magnetite reduces selenite to FeSe and Fe$_7$Se$_8$ species at pH 5. Siderite is weakest catalyst of three minerals and only partially reduces selenite to Se(0) (Scheinost and Charlet, 2008).

Montmorillonite equilibrated with Fe^{2+} is able to catalyze the slow reduction of selenite [Se(IV)] to nanoparticulate Se(0) (Charlet et al., 2007). Mossbauer and XAS spectroscopy suggest that the Se and Fe redox reactions are not directly coupled, but rather that a small amount of Fe(II) that is presorbed on the montmorillonite is oxidized to Fe(III), and the electrons that are produced during this reaction are stored by the formation of surface H$_2$ species, which then later are able to reduce selenite (Charlet et al., 2007).

18.4.1.3 Iron

Manganese oxides, which have different structural and surface properties, vary in their ability to catalyze the conversion of Fe(II) to Fe(III) and the subsequent formation of Fe oxides and oxyhydroxides (Krishnamurti and Huang, 1987, 1988). The standard electrode potential (E°) of the redox pairs Fe^{2+}–MnO$_2$ and Fe^{2+}–Mn$_3$O$_4$ can be described by the following equations (Bricker, 1965):

$$2Fe^{2+} + MnO_2 + 4H^+ = Mn^{2+} + 2Fe^{3+} + 2H_2O \quad E° = +0.438\,V,$$

(18.15)

$$2Fe^{2+} + Mn_3O_4 + 8H^+ = 3Mn^{2+} + 2Fe^{3+} + 4H_2O \quad E° = +1.04\,V.$$

(18.16)
These *E*° values indicate that oxidation of Fe^{2+} by Mn oxides is thermodynamically feasible. The Eh–pH diagram (Figure 18.13) indicates the feasibility of the conversion of Mn^{4+} and Mn^{3+} to Mn^{2+} in the Mn oxides in the Eh–pH ranges of the formation of Fe oxides and oxyhydroxides. Further, the ESR spectra of the filtrates after the reaction of Fe^{2+} with Mn oxides show the presence of a significant amount of Mn^{2+}, demonstrating the reduction of Mn(IV) and Mn(III) oxides to Mn^{2+} in the presence of Fe^{2+} in solution. Simultaneously, the oxidation of Fe^{2+} to Fe^{3+} by Mn oxides leads to subsequent hydrolysis of Fe^{3+} to form a series of the precipitation products including lepidocrocite, akaganeite, feroxyhyte, and magnetite. Because various Mn oxides differ in their ability to catalyze the formation of Fe oxides and oxyhydroxides, their role in the transformation of Fe deserves attention.

At neutral pH conditions, structural Fe(III) in hematite is able to catalyze the oxidation of sorbed Fe(II) to amorphous ferric oxide on the surface of hematite (Jeon et al., 2003). Solid-phase contact among hematite, amorphous ferric oxide, and structural Fe(II) eventually produces magnetite (Fe$_3$O$_4$) (Jeon et al., 2003). Hydrous ferric oxide is able to catalyze the abiotic oxidation of
FIGURE 18.13 Stability relations of different species of Mn at 25°C, 0.101 MPa, and a$_{Mn^{2+}}$ = 10^{-6} (Bricker 1965). The Eh and pH ranges of the systems during the formation of iron oxide precipitates in the presence of Mn oxides in the present study are shown as shaded region. (Reprinted from Krishnamurti, G.S.R., and P.M. Huang. 1988. Influence of manganese oxide minerals on the formation of iron oxides. Clay. Clay Miner. 36:467–475. With permission of the Clay Minerals Society.)

Fe^{2+} under anoxic conditions at neutral pH (Park and Dempsey, 2005). During this reaction, the hydrous ferric oxide is partially converted to goethite. The reaction mechanism involves an anode/cathode mechanism with O$_2$ reduced at electron deficient sites with Fe(II) strongly sorbed, and Fe(II) is oxidized at electron-rich sites without sorbed Fe(II). Iron(III) has been found to play a dominant role in pyrite (FeS$_2$) oxidation in comparison with dissolved oxygen under acidic conditions (Mazumdar et al., 2008).

18.4.1.4 Manganese

Although oxidation of Mn in soils by atmospheric O$_2$ is a thermodynamic possibility throughout the pe and pH range common in well-aerated soils, Mn is not readily oxidized in solutions unless the pH is raised above pH 8.5 (Ross and Bartlett, 1981). A catalytic mechanism of some sort is apparently necessary. Oxidation of Mn in soil environments is generally assumed to be microbially mediated (Tebo et al., 2005; Thompson et al., 2005).

Oxidation of Mn(II) by soils has been shown to be proportional to the level of existing reactive Mn oxides (Ross and Bartlett, 1981). Arrhenius plots of rates of the oxidation between 1°C and 35°C show that the oxidation of Mn(II) by soils has nonbiological characteristics. Generally, oxidation of Mn(II) is initially rapid with no lag period and may be related to the mechanism proposed for the accumulation of Co and Zn on Mn oxide surfaces (Loganathan et al., 1977). The adsorption on

the oxide surfaces is specific and not a simple function of surface charge. Above pH 5–6, this adsorption reverses the surface charge of the Mn oxides from negative to positive, as measured by electrophoretic mobility. A positively charged surface should result in a higher OH^- concentration near the surface, which could enable oxidation of adsorbed Mn(II) by atmospheric O_2. The mechanism of specific adsorption is not fully understood, but the preferential adsorption of transition metals by Mn oxides is well documented (Jenne, 1977). The oxidation of Mn(II) by Mn oxides is theorized to be autocatalytic, involving specific adsorption of Mn(II) on existing Mn oxide surfaces (Ross and Bartlett, 1981).

The Fe(III) oxyhydroxide, akaganeite, promotes the formation of birnessite (δ-MnO_2) by catalyzing the air oxidation of surface adsorbed Mn(II) (Cornell and Giovanoli, 1991). Hematite, especially at a particle size below 4 nm, is able to promote the oxidation Mn(II) in the presence of O_2 by donating electron density to adsorbed Mn^{2+}, which promotes reaction with O_2 (Madden and Hochella, 2005).

18.4.1.5 Radionuclides

Radionuclides are unstable isotopes of elements that are radioactive. Most elements with an atomic number greater than 83 have an unstable nucleus and are thus radioactive, and therefore, all of their isotopes are radionuclides. Many radionuclides are man-made, for example, plutonium and technetium, and are released into the environment as a result of nuclear waste, airborne emissions from nuclear reactors, nuclear weapons testing and processing, and infrequently due to incorrect disposal of medical or industrial radiation sources (Salbu et al., 2004; USEPA, 2009). Most of the commonly encountered polluting radionuclides have multiple oxidation states, and thus, redox chemistry plays a dominant role in their environmental mobility and availability.

Plutonium and neptunium are the chief radionuclides of concern for long-term storage of nuclear waste due to their long half-lives ($t_{1/2} = 2.14 \times 10^6$ years for ^{237}Np and 2.41×10^4 years for ^{239}Pu), radiotoxicity, and chemotoxicity (Runde et al., 2002). Plutonium exists in the III–VI oxidation states as Pu^{3+}, Pu^{4+}, PuO_2^+, and PuO_2^{2+} in strong acid conditions. Plutonium(III/IV) cations are sorbed by soil constituents, and therefore, immobile in most aqueous and soil environments, whereas, Pu(VI) cations are not sorbed by temperate soils and thus quite mobile and bioavailable. $Pu(V)O_2^+$ can be sorbed onto soil surfaces from dilute solutions or seawater (Keeneykennicutt and Morse, 1985). Neptunium tends to occur as highly mobile $Np(V)O_2^+$ oxidation state under a wide range of environmental conditions (Wilk et al., 2005).

Manganese(III/IV) oxides and oxyhydroxides can oxidize Pu(III/IV) (Cleveland, 1970; Amacher and Baker, 1982; Morgenstern and Choppin, 2002) and Pu(V) (Keeneykennicutt and Morse, 1985; Duff et al., 1999) to the more mobile and toxic Pu(VI). Conversely, Mn(II)-bearing oxides, hausmannite and manganite, can reduce Pu(VI) to Pu(IV), which then forms strong inner-sphere complexes with the surface of the mineral

(Shaughnessy et al., 2003). Surprisingly, it has also been shown that pyrolusite (α-MnO_2), a Mn(IV)-bearing oxide, can promote the reduction of Pu(VI) (Kersting et al., 1999; Powell et al., 2006). Powell et al. (2006) attributed this to the observation that pyrolusite can initially oxidize Pu(IV) to Pu(VI); however, if the oxidized species remains associated with the solid phase, the initial oxidation step is followed by reduction to a stable hydrolyzed Pu(IV) species, which is not affected by the oxidizing surface, and over time becomes the predominant solid-phase Pu species. These findings are important when assessing the risk of the geological burying of nuclear waste in areas containing Mn(IV)-bearing minerals, such as Yucca Mountain or the Hanford sites (Powell et al., 2006).

Iron(II)-bearing minerals can reduce highly mobile Np(V) and Pu(V/VI) species, as well as, many other mobile higher valency species of radionuclides such as uranium and technetium. Natural uranium is mildly radioactive and occurs in trace amounts in most rocks, soils, and water. The more strongly radioactive isotope, U-235, is selectively enriched and used for nuclear weapons and for fuel for nuclear reactors. The U-235-depleted uranium is used for making weapons and armor, and has been used for counter weights in aircraft tails. All the above-mentioned uses result in the release of U into the environment. Similar to Pu and Np, U has a variety of oxidation states with uranyl $U(VI)O_2^{2+}$ species being the most mobile. Technetium is an artificial element produced during nuclear fission and is commonly found in groundwater at sites where nuclear waste has been processed or stored. It has a similar chemistry to Mn and has several oxidation states. Under oxic conditions, it occurs as a pertechnetate anion, $Tc(VII)O_4^-$, which is poorly sorbed across the environmental pH range. The lower valency Tc(IV) readily precipitates as insoluble hydrous oxides or is sorbed on mineral surfaces.

Magnetite (Fe_3O_4) can reduce Pu(V) to strongly sorbed Pu(IV) over a wide pH range (pH 3–8; Powell et al., 2004). Similarly, magnetite can reduce Tc(VII) to Tc(IV) (Cui and Eriksen, 1996), Np(V) to Np(IV) (Nakata et al., 2004), and U(VI) to U(IV) (Scott et al., 2005; El Aamrani et al., 2007). Biotite, which contains significant amounts of Fe(II), is also able to reduce U(VI) on exposed edge sites over a broad pH range (Ilton et al., 2004).

Green rusts, which are mixed Fe(II/III) hydrous oxides, are potent reducing agents in suboxic environments and can readily reduce U(VI) to U(IV) to precipitate nanoparticular UO_2 (O'Loughlin et al., 2003a) and reduce Tc(VII) pertechnetate anions to strongly surface-complexed Tc(IV) (Pepper et al., 2003). Likewise, amorphous FeS can reduce U(VI) to U(V) and U(IV) oxides (Hua and Deng, 2008). Mackinawite (FeS) is able to reduce Tc(VII) to form $Tc(IV)S_2$, U(VI) to U(V/IV) oxide phases, and Np(V) to Np(IV) surface complexes (Livens et al., 2004).

Fe(II) sorbed to the surface of Fe(III)-containing oxides, forming the reactive surface species $\equiv Fe^{III}O$–$Fe^{II}OH^0$, is also a potent reducing agent of radionuclides. In contrast to the abiotic reduction of organics (e.g., nitrobenzenes) by Fe(II) sorbed to hematite or magnetite, which is an outer-sphere mechanism, the

reduction of inorganics such as U(VI) involves an inner-sphere electron transfer mechanism (Charlet et al., 1998; Liger et al., 1999). The first step is the adsorption of U(VI) ion by the reactive surface species and the formation of an inner-sphere complex, followed by two reductive steps, which lead to the formation of a mixed $U(IV)O_2/Fe(OH)_3$ solid phase (Charlet et al., 1998; Liger et al., 1999). The reduction of U(VI) by Fe(II) sorbed to synthetic Fe oxides (magnetite, goethite, and hematite) and natural Fe(III) oxide-containing sediments has been demonstrated, and the natural sediments are less efficient than the pure oxides due to their lower Fe(II) sorption capacity (Jeon et al., 2005). Iron(II) sorbed to hematite and goethite is much more efficient Tc(VII)-reducing agent than Fe(II) sorbed to phyllosilicates (vermiculite, illite, and muscovite) or structural Fe(II) in the phyllosilicates (Peretyazhko et al., 2008a). Iron(II) sorbed to Al oxyhydroxide, diaspore, and Al oxide, corundum, is also able to reduce Tc(VII) to insoluble Tc(IV) (Peretyazhko et al., 2008b).

Natural humic substances and quinoid-enriched humic substances are able to catalyze the abiotic reduction of Pu(V) to insoluble Pu(IV) over a wide pH range and under oxic and anoxic conditions (Andre and Choppin, 2000; Shcherbina et al., 2007a). Humic substances are only able to reduce Np(V) to Np(IV) under acidic, anoxic conditions (Shcherbina et al., 2007a, 2007b).

18.4.1.6 Other Trace Metals

In addition to oxidation of metalloids such as As(III) and metals such as Fe(II), Mn(II), Mn oxides, and oxyhydroxides can catalyze the oxidation of trace metals by disproportionation of Mn^{2+} and MnO_2. The disproportionation facilitates electron transfer processes that can either greatly decrease or increase the equilibrium solubility of certain metals (Hem, 1978).

Chromium and Pu are similar in chemical behavior in aqueous environments (Rai and Serne, 1977; Bartlett and James, 1979). Chromium occurs in the II, III, and VI oxidation states in water. Chromium(II) is unstable. Chromium(III) has broad stability and exists as the cation Cr^{3+} and its hydrolysis products or as the anion CrO_2^-. Chromium(VI) exists under strongly oxidizing conditions, occurs as dichromate $Cr_2O_7^{2-}$, or chromate $HCrO_4^-$ and CrO_4^{2-} anions. Chromium(III) cations are readily sorbed to soil constituents, and therefore, immobile in most aqueous and soil environments; however, Cr(VI) is not sorbed by temperate soils to any extent and is thus quite mobile in soils and associated aqueous environments. Therefore, hexavalent Cr is readily bioavailable and extremely toxic (Amacher and Baker, 1982) and, thus, of concern in food-chain contamination and ecosystem health. Manganese(III/IV) oxides can oxidize Cr(III) and are the only known oxidizers of Cr(III) in the soil environment (Stepniewska et al., 2004; Negra et al., 2005).

The kinetics of Cr(III) oxidation by Mn oxide is very rapid with most of the conversion of Cr(III) to Cr(VI) occurring during the first hour (Amacher and Baker, 1982). The oxidation of Cr(III) increases with increasing temperature. Manganite (γ-MnOOH) is also able to catalyze the oxidation of Cr(III), and the reaction rate increases under acidic conditions (Weaver et al., 2002). At higher

pH, Cr(III) hydroxy hydrate precipitates on the manganite surface, and the oxidation reactions are minimized (Weaver et al., 2002). Feng et al. (2007) compared the Cr(III) oxidative power of four different Mn oxides and found that order of reactivity was as follows (mmol Cr(III) kg^{-1} oxide): birnessite (1330.0) > cryptomelane (422.6) > todorokite (59.7) > hausmannite (36.6). The Cr(III) oxidative ability of the Mn oxides depends on the crystallinity, structure, composition, and surface properties of the minerals (Feng et al., 2007).

The kinetics of Cr(III) oxidation on Mn(III/IV) oxides shows a trend similar to that observed for soils (Amacher and Baker, 1982). Negra et al. (2005) demonstrated that greater Mn(IV) oxide abundance in soils enhances the Cr(III) oxidation potential. It has also been shown that the oxidation state of Cr in soils in the long-term depends on balances between organic carbon availability (enhances Cr reduction) and the Mn redox status [Mn(III)/(IV) oxides enhance oxidation] (Stepniewska et al., 2004; Tokunaga et al., 2007). Nonliving biomaterials, such as seaweed, dead fungi, sawdust and pine bark, and needles, are able to abiotically (nonenzymatically) catalyze the adsorption-coupled reduction of Cr(VI) to Cr(III) (Park et al., 2004, 2007, 2008b). The Cr(VI)-reducing capacity of pine bark is 8.7 times higher than that of a common chemical Cr(VI) reductant, $FeSO_4 \cdot 7H_2O$. When Cr(VI) comes in contact with biomaterials, there are two possible reduction mechanisms (Figure 18.14) (Park et al., 2005, 2007). Mechanism I, the direct reduction mechanism, involves the direct reduction of Cr(VI) to Cr(III) by contact with electron-donor groups of the biomaterial, such as amino and carboxyl groups (Figure 18.14). Mechanism II, the indirect reduction mechanism, involves three steps: (1) the binding of anionic Cr(VI) to the positively charged groups present on the biomaterial surface, (2) the reduction of Cr(VI) to Cr(III) by adjacent electron-donor groups, and (3) the release of the reduced Cr(III) into the aqueous phase due to electronic repulsion between the positively charged groups and the Cr(III), or the complexation of the reduced Cr(III) with adjacent groups (Figure 18.14). A lower pH makes the biosurface more positively charged and accelerates redox reactions, which enhances Cr(VI) removal (Park et al., 2007). The addition of soil slurry to nonliving biomaterials, such as pine bark, significantly enhances the Cr(VI)-reducing capability of the pine bark, by sorbing Cr(III) from solution (Park et al., 2008a). Therefore, although Mn oxides can enhance the mobility and toxicity of Cr in soils and related environments, the presence of organic matter decreases its oxidation potential.

Manganese oxides and oxyhydroxides can also catalyze the oxidation of other trace metals such as Co, Pb, Ni, Cu (Hem, 1978), and Sb (Belzile et al., 2001). The catalytic transformation of these metal ions may be directly influenced by redox processes coupled to disproportionation of Mn mixed valence oxide, to catalyzed oxidation by aqueous O_2, or to other redox reactions involving changes from one Mn oxide species to another. When the oxidized form of the element has a lower solubility than the reduced form, this effect can be of major significance.

X-ray photoelectron spectroscopy measurements of Co adsorbed on MnO_2 reveal strong evidence that Co(II) is oxidized

to Co(III) in the presence of the strong electric field at the MnO$_2$–solution interface (Murray and Dillard, 1979). Nickel(II), however, cannot be oxidized at the interface except at very high concentrations. Strong experimental evidence for the oxidation of other trace metals catalyzed by Mn oxides still remains to be attained. Further, more information on the kinetics and mechanisms of redox reactions of these trace metals on the surfaces of Mn oxides is needed.

Other than Mn oxides, heterogeneous oxidation/reduction reactions involving electron transfer between transition metals and Fe-containing minerals have been investigated in numerous studies. Vanadium(II) and V(IV) can be oxidized by Fe(III) oxyhydroxides (Wehrli and Stumm, 1989). Amorphous Fe(III) oxyhydroxides present in natural waters and sediments can also oxidize the more toxic Sb(III) into Sb(V) (Belzile et al., 2001). The oxidation pseudo-first-order rate of Sb(III) by natural Fe oxyhydroxides is slower compared to synthetic Fe oxyhydroxides. This is attributed to the slight crystallinity of the natural oxides (compared to amorphous synthetic compounds) and to their more complex chemical composition, which can include adsorbed ions and organic matter (Belzile et al., 2001). Goethite has also been shown to catalyze the oxidation of Sb(III) to Sb(V) (Leuz et al., 2006).

Iron(II)-bearing minerals are able to reduce a variety of trace metals. Reduction of Cr(VI) by biotite has been shown by Eary and Rai (1989) and Ilton and Veblen (1994). Magnetite and ilmenite are the most common Fe(II)-containing oxide minerals in the earth's crust and potentially important in controlling heterogeneous redox reactions involving aqueous transition metals in soil environments. Direct evidence of Cr(VI) reduction on magnetite surfaces has been documented by Peterson et al. (1996) using x-ray adsorption fine structure (EXAFS)

spectroscopy. Structural Fe(II) in magnetite and ilmenite heterogeneously reduces aqueous Cu(II), V(IV), and Cr(VI) ions at the oxide surfaces over a pH range of 1–7 at 25°C (White and Peterson, 1996). Calcium carbonate coatings on the surface of magnetite reduce or eliminate its ability to reduce Cr(VI) (Doyle et al., 2004). Siderite (FeCO$_3$) is also able to reduce aqueous Cr(VI), and its reactivity increases with addition of acid and with increasing temperature (Erdem et al., 2004). Pyrite is also an effective reductant of Cr(VI), and the reaction is about 100 times faster than reduction by biotite, which is related to the relative amount and dissolution rate of Fe(II) from the minerals (Chon et al., 2006). Similarly, Lin and Huang (2008) investigated the kinetics and effect of solution characteristics on Cr(VI) reduction by pyrite under dark and anaerobic conditions and found that the reduction is highly dependent on the solution pH, which influences the dissolution of Fe(II) and sulfide ions from pyrite, which are responsible for the reduction of Cr(VI). Magnetite (within days) and mackinawite (within minutes) are able to reduce Sb(V) to the more toxic Sb(III) form (Kirsch et al., 2008). The Sb(V) reduction by mackinawite proceeds solely by oxidation of surface Fe(II), while the oxidation state of sulfide is conserved, with the formation of amorphous or nanoparticulate SbS$_3$-like solids (Kirsch et al., 2008).

The Fe(II)-rich chlorite and corrensite clays are able to reduce Cr(VI) under acidic conditions, and during the reaction, structural Fe(II) is oxidized to Fe(III) (Brigatti et al., 2000). Mixed Fe(II)/Fe(III) hydroxides, known as green rusts, commonly found in suboxic environments are able to readily reduce a variety of trace metals, such as Ag(I), Au(III), Cu(II), and Hg(II) to Ag(0), Au(0), Cu(0), and Hg(0) (O'Loughlin et al., 2003b). Sulfate green rusts are able to effectively reduce Cr(VI) to Cr(III), which

initially involves chromate anions replacing sulfate in the interlayer of the green rust, and then the chromate is reduced by Fe(II) (Skovbjerg et al., 2006). Even though the formation of sparing soluble Cr(III) blocks further chromate entry, Cr(VI) reduction continues at the green rust solid/solution interface due to electron transfer from the center of the green rust crystals. During this process, Cr-substituted goethite is formed, which is sparingly soluble and thus essentially locks away the Cr, which has important implications for environmental remediation (Skovbjerg et al., 2006). Sulfate green rust is also able to reduce the highly stable Sb(V) to the more toxic Sb(III) (Mitsunobu et al., 2008).

Iron(II) sorbed to the surface of Fe oxides and clay minerals are also able to catalyze the reduction of Cr(VI) to Cr(III). Buerge and Hug (1999) compared the Cr(VI) reduction reactivity of Fe(II) in the presence of aluminum oxide, silicon dioxide, goethite, lepidocrocite, montmorillonite, and kaolinite and found that only Al_2O_3 did not accelerate the reduction reaction in the presence of Fe(II). The order of reactivity was as follows (Buerge and Hug, 1999): goethite ≈ lepidocrocite ≫ montmorillonite > kaolinite ≈ SiO_2 ≫ Al_2O_3. Similarly, Fe(II) added to magnetite significantly improves the Cr(VI) reductive ability of magnetite (Jung et al., 2007).

Organic complexes of Fe(II) also strongly affect the reduction of Cr(VI) to Cr(III) (Buerge and Hug, 1998). Fe(III)-stabilizing ligands such as bi- and multidentate carboxylates and phenolates generally accelerate the reduction reaction, whereas Fe(II)-stabilizing ligands such as phenanthroline essentially stop the reaction. Natural dissolved organic matter from a forest soil shows quantitatively the same accelerating behavior as the investigated Fe(II)-carboxylate complexes (Buerge and Hug, 1998).

18.4.2 Transformation of Other Inorganics

Nitrate formation in soils from NO_2^- is related to soil level of reactive Mn oxides, which catalyze the oxidation (Bartlett, 1981). Nitrite oxidation, NO_3^- formation, and MnO_2 reduction are stoichiometrically related reactions both in the presence and the absence of atmospheric O_2. The relationship shown in Figure 18.15 suggests that at high ratios of MnO_2/NO_2^-, most of the Mn(IV) is reduced only to nonexchangeable solid Mn(III) oxide rather than to exchangeable Mn(II) ions. When the MnO_2/NO_2^- ratio is high, little Mn(II) becomes exchangeable relative to the NO_3^- formed, as indicated by high values of $NO_3^-/Mn(II)$. At low MnO_2/NO_2^- ratios, more exchangeable Mn(II) relative to NO_3^- is formed. Therefore, the more MnO_2 relative to NO_2^-, the greater is the efficiency of the NO_2^- to NO_3^- transformation and the less exchangeable Mn(II) formed relative to NO_3^-. High MnO_2/NO_2^- ratios likely prevail in many soils. Equation 18.17, which does not involve a pH change, may describe the NO_2^- to NO_3^- transformation in high Mn oxide soils better than Equation 18.18:

$$NO_2^- + 2MnO_2 = Mn_2O_3 + NO_3^-, \qquad (18.17)$$

$$NO_2^- + MnO_2 + 2H^+ = Mn^{2+} + NO_3^- + H_2O. \qquad (18.18)$$
FIGURE 18.15   The logs of the ratios of nitrate formed from nitrite over Mn reduced to the exchangeable form plotted against the MnO_2/nitrite ratios in the original suspensions. (Reprinted from Bartlett, R.J. 1981. Nonmicrobial nitrite-to-nitrate transformation in soils. Soil Sci. Soc. Am. J. 45:1054–1058. With permission of the Soil Science Society of America.)

Such a process of substantial reduction of Mn in the solid phase relative to the release of exchangeable Mn(II) might be described better as the insertion of electrons into the overlapping electronic orbitals of the solid, such that the electron excess is delocalized over the solid, rather than the reduction of one Mn^{4+} atom to Mn^{2+} at a particular surface site. The overlapping atomic orbitals form bands of many energy levels rather than a single energy level.

Luther and Popp (2002) studied the kinetics of nitrite oxidation by polymeric Mn(IV) oxides, which are highly reactive Mn oxide phases. The energy of activation and the entropy of activation show the oxidation reaction to be associative and diffusion controlled, occurring via an inner-sphere mechanism, likely with O atom transfer from MnO_2 to HNO_2. The reaction requires protons and slows down at a pH above 5.5, where NO_2^- and MnO_2 (negatively charged) become the dominant species (Luther and Popp, 2002).

Manganese(IV) oxide is also able to catalyze the oxidation of NH_3 and organic N to N_2, which has traditionally been assumed to be a microbially mediated process in sediments (Luther et al., 1997). The MnO_2-catalyzed formation of NO_3^{2-} from NH_3 can also occur, but the formation of N_2 from NH_3 is more favorable (Luther et al., 1997). Luther et al. also observed the reduction NO_3^{2-} to N_2 by dissolved Mn^{2+}. These oxidation and reduction reactions can occur in the presence or absence of O_2. Hulth et al. (1999) found that introduction of Mn oxides from oxidized surface sediments into anoxic sediments results in anoxic nitrification and the net production of NO_3^- and NO_2^-. They found that the anoxic nitrification rates were directly related to the Mn oxide content of the sediment.

Iron(II)-bearing minerals can catalyze the abiotic reduction of nitrate and nitrite. Some field studies have suggested that structural Fe(II) in clay minerals catalyzes the reduction of NO_3^- to NO_2^-, as indicated by significant negative correlations in the

NO_3^- and Fe(II) content in minerals in clayey till and catchment sediments (Ernstsen and Morup, 1992; Ernstsen, 1996). Chloride and sulfate intercalated green rusts (mixed Fe(II/III) hydrous oxides), which commonly occurs in anaerobic soils and sediments, are able to rapidly reduce NO_3^- to NH_4^+ NH_4^+, with the formation of magnetite (Fe_3O_4) (Hansen et al., 1996; Hansen and Koch, 1998; Hansen et al., 2001). Wustite (FeO) is able to catalyze the rapid reduction of NO_3^{2-} to NO_2^- and ultimately NH_4^+ (Rakshit et al., 2005). During this reaction, an Fe(II/III) oxide, magnetite (Fe_3O_4), is formed. Siderite ($FeCO_3$) is able to catalyze the abiotic reduction of NO_2^- to N_2O, during which siderite is transformed to lepidocrocite (γ-FeOOH) (Rakshit et al., 2008).

Nitrate immobilization into dissolved and humic organic N fractions can be abiotically catalyzed in soils and sediments (Dail et al., 2001; Davidson et al., 2003; Huygens et al., 2008; Torres-Canabate et al., 2008). It has been suggested that anaerobic microsites in soils that contain reduced Fe and Mn minerals are responsible for catalyzing the reactions (Davidson et al., 2003; Torres-Canabate et al., 2008). The mechanism is thought to involve the abiotic reduction of NO_3^{2-} by Fe(II) (present in anaerobic microsites) to NO_2^-, which then rapidly abiotically reacts with existing organic matter via nitrosation (Thorn and Mikita, 2000) and thus is incorporated into the organic N fraction (Davidson et al., 2003). Further research is required to elucidate the exact mechanism of abiotic nitrate immobilization into organic N.

Manganese oxides also catalyze the oxidation of gaseous CO (Klier and Kuchynka, 1966). This reaction occurs by consumption of the structural O_2^{2-} of MnO_2. The catalyst must then be regenerated by chemisorption of O_2. Whether or not a similar cycle of Mn oxide reduction and O_2 consumption occurs in soil environments, where adsorbed molecules such as CO_2 and H_2O can poison the catalyst surface, remains unanswered.

Soil clay minerals and metal oxides, such as montmorillonite and goethite, can catalyze the abiotic hydrolytic degradation of high- and low-molecular-weight silicones, such as polydimethylsiloxane, by cleaving siloxane (Si–O–Si) bonds (Graiver et al., 2003). The resultant low-molecular-weight silanol units are volatile and thus evaporate into the atmosphere where they are degraded to silica, water, and CO_2 by hydroxyl-free radicals in the atmosphere (Graiver et al., 2003).

18.5 Role of Nanoparticles in Abiotic Catalysis

Mineral nanoparticles are important constituents of natural terrestrial and aquatic environments (Gilbert and Banfield, 2005; Waychunas et al., 2005; Wigginton et al., 2007; Hochella et al., 2008; Wilson et al., 2008). Iron oxides, oxyhydroxides, and sulfides commonly occur as nanoparticles in nature; and various studies have investigated the abiotic transformation of organics (Klupinski et al., 2004; McCormick and Adriaens, 2004; Chun et al., 2006; Cwiertny et al., 2008) and inorganics, such as Sb (Kirsch et al., 2008) and Se (Loyo et al., 2008; Scheinost and Charlet, 2008) by nanoparticulate Fe-bearing minerals.

Mineral nanoparticles exhibit considerably different chemical and physical properties than their larger counterparts, due to the fact that a large percentage of their atoms are on the surface (e.g., for a particle with a diameter of 4 nm approximately 50% of its atoms are on the surface) (Grassian, 2008; Hochella et al., 2008). This can result in surface strain or reconstruction (relaxation), structural disorder, and variations in surface topography and crystallographic structure that is exposed. Although nanoparticles are highly reactive, which is attributable to their very high specific surface area, it has become clear that their increased reactivity cannot be solely attributed to this characteristic. Surface area-normalized studies have reported enhanced nanoparticle reactivity such as cation adsorption and redox reactions, which could only be attributed to a greater density of reactive sites per surface area unit or a greater inherent reactivity of nanoparticle surface sites (Waychunas et al., 2005; Grassian, 2008; Hochella et al., 2008).

Several studies have shown that the reactivity of Fe oxides and oxyhydroxides, which commonly occur as nanoparticles (3–10 nm range), is strongly dependent on particle size. The surface area-normalized reductive dissolution of 4 nm particles of ferrihydrite by hydroquinone is 20 times faster than that of 6 nm particles (Anschutz and Penn, 2005). Similarly, Erbs et al. (2008) investigated the effect of particle size on reductive dissolution of nanoparticulate ferrihydrite by hydroquinone, and they attributed the increased reactivity to increased reagent-surface encounters as indicated by a sixfold increase in the pre-exponential factor when comparing 3.9 nm particles to 5.9 nm particles. They hypothesized that the rate of diffusion of the reagent to the nanoparticle surface is size dependent, as the structure of the water is affected by the size of the nanoparticle.

Nanoparticulate hematite oxidation of soluble Mn^{2+} in the presence of O_2 is dependent on the size of the nanoparticles as related to surface structure and topography (Madden and Hochella, 2005). The surface area-normalized oxidation rate of hematite particles with an average diameter of 7.3 nm is at least one order of magnitude higher than those with an average diameter of 37 nm. The oxidation reaction proceeds most readily at topographic features that distort the octahedral Mn^{2+} coordination environment. These distorting surface features increase as the particle size of hematite decreases. This has the effect of lowering the reorganization energy, which effectively controls the magnitude of the transition state barrier (Madden and Hochella, 2005).

Particle diameter of nanoparticulate magnetite strongly affects its reactivity toward the reductive degradation of carbon tetrachloride (Vikesland et al., 2007). Magnetite with a 9 nm diameter is far more reactive than 80 nm diameter magnetite on both a mass and surface area-normalized basis. The aggregation state of the 9 nm magnetite significantly affects its reactivity, and an increase in ionic strength leads to a decrease in reactivity due to increased aggregation of the nanoparticles. Jung et al. (2008a) compared the reactivity of biogenic and commercial nanoparticulate magnetite toward catalyzing the ozonation of parachlorobenzoic acid. Biogenic magnetite was found to be a less

efficient catalyst due to its tendency to form larger aggregates than the commercial magnetite (Jung et al., 2008a). While investigating the abiotic reductive transformation of nitrobenzene by Fe(II)-sorbed on goethite nanoparticles, Cwiertny et al. (2008) found that aggregation of the goethite nanoparticles resulted in the decreased BET-specific surface area-normalized rate constants, implying that they are less reactive than larger particles. They concluded that new methods are needed to quantify the amount of surface area accessible for reaction in wet nanoparticle suspensions rather than assuming the specific surface area of the dry nanoparticles is relevant.

In view of the high specific surface area and the density and nature of reactive sites of nanoparticles, their role in the catalytic reactions in soil and related environments merits increasing attention for years to come.

18.6 Conclusions

The significance of abiotic catalysis in the transformation of natural organic, anthropogenic organic compounds, metals, metalloids, and other inorganics is far greater than had previously been perceived. Mineral colloids are abundant in nature. Abiotic catalysts include metal (oxy)hydroxides and oxides, SRO aluminosilicates, layer silicates, and primary minerals. The ability of these catalysts to promote the transformation of vital elements and environmental pollutants varies significantly with their atomic bonding and structural configuration and surface chemistry and the structure and functionality of the substrates.

The transformation of biomolecules to humic substances is substantially promoted by abiotic catalysis. Phenolics are the most widely distributed class of plant secondary metabolites and play an important role in regulating nutrient cycling in the terrestrial environment. Abiotic catalysis promotes the formation of humic substances from the phenolic compounds especially in the presence of the amino acids through oxidative polymerization, polycondensation, ring cleavage, decarboxylation, dealkylation, and/or deamination. Sugars and amino acids are among the most abundant constituents of the terrestrial ecosystem. The Maillard reaction, involving condensation reactions between reducing sugars and amino acids, is substantially promoted by abiotic catalysis. In nature, the Maillard reaction and polyphenol pathways should interact closely, since sugars, amino acids, and polyphenols coexist in soil solutions and natural waters. The integrated polyphenol–Maillard reaction system under abiotic catalysis is more effective in generating humic polymers than the Maillard reaction or the polyphenol pathway alone. A series of mineral colloids promotes such catalytic reactions. Among abiotic catalysts, Mn oxides are most reactive in the transformation of these biomolecules.

Mineral colloids can catalyze the hydrolysis of many xenobiotics through the ability of their metal-containing surfaces to behave as Brønsted acids and donate protons or to act as Lewis acids and accept electron pairs. The catalytic effectiveness of a metal ion depends on its ability to complex reactant molecules and shift electron density and conformation in ways favorable to the reactions. A wide range of xenobiotics such as pesticides, antibiotics, dyes, and explosives are subject to abiotic soil mineral-catalyzed oxidative transformation. In anoxic groundwater and surficial waters, biogeochemical processes provide a variety of potential reductants to catalyze abiotic transformation of persistent xenobiotics. Abiotic degradation pathways of biocides (pesticides and antibiotics) are particularly important in the environment as the toxicity of these substances can limit their biotic degradation. Much is known about the toxicity of xenobiotic parent compounds. To date, relatively little is known about the bioavailability and toxicity of xenobiotics after reaction with abiotic catalysts, such as metal (oxy)hydroxides and oxides and clay minerals.

The transformations of metals and metalloids are substantially influenced by Mn oxides and Fe-bearing minerals. Manganese(IV) oxides have the ability to catalyze many reactions such as the oxidation of As(III) to As(V), Fe(II) to Fe(III), Pu(III, IV, V) to Pu(VI), and Cr(III) to Cr(IV). The ability of Mn(IV) oxides to catalyze these transformation reactions varies with their structure and surface properties and can also be influenced by the kinds and levels of surface coatings. Iron(III)-bearing minerals also have the ability to catalyze the oxidation of some transition metals such as the transformation of V(II) to V(IV) and Sb(III) to Sb(V). On the other hand, the ability of Fe(II)-bearing minerals to catalyze the reduction reactions of a variety of trace metals and metalloids (e.g., Cr, Sb, V, Hg, U, Tc, Pu, Np, and Se) has been demonstrated. Besides Fe(II)-bearing minerals, nonliving biomaterials are able to abiotically catalyze the adsorption-coupled reduction of Cr(VI) to Cr(III). The solubility, mobility, toxicity, and food-chain contamination of metals and metalloids can be significantly influenced by abiotic catalysis.

Manganese(IV) oxides have been shown to catalyze the conversion of NO_2^- to NO_3^-. The reaction is theorized as mainly the insertion of electrons from NO_2^- into the overlapping electron orbitals of the Mn oxides. Manganese(IV) oxides also catalyze the oxidation of gaseous CO through consumption of structural O_2^-. Furthermore, nitrate immobilization into dissolved and humic organic N fractions can be abiotically catalyzed by reduced Fe and Mn (present in anaerobic microsites) in soils and sediments. Further research is required to elucidate the exact mechanism of nitrate immobilization into organic N.

Nanoparticles are important environmental particles, which influence the pedosphere, hydrosphere, biosphere, and atmosphere. Mineral nanoparticles exhibit considerably different chemical and physical properties, compared with their larger counterparts. This is ascribed to the exposure of a large percentage of atoms on the surface of nanoparticles and the resultant high specific surface area and the increase in density and reactivity of reactive sites of nanoparticles. The catalytic role of mineral nanoparticles in the transformation of organics and inorganics has been demonstrated. More in-depth research on the abiotic catalysis of environmental nanoparticles and on the biogeochemical and ecological impacts is warranted.

Therefore, abiotic catalysis deserves close attention in sustaining environmental quality and ecosystem health. Furthermore, abiotic and biotic catalysts coexist in soil and associated environments. Abiotic catalysts can influence microbial formation of enzymes (biotic catalysts) and enzymatic activity. The interactions and relative importance of abiotic and biotic catalysts and the impact on terrestrial ecosystem integrity should, thus, be an important and exciting issue for years to come.

Soil pH and pH Buffering

Paul R. Bloom
University of Minnesota

Ulf Skyllberg
Swedish University of Agricultural Sciences

19.1 Introduction

Soil pH is a measure of soil acidity or alkalinity and is probably the single most important chemical characteristic of a soil. In the past, soil acidity or alkalinity, reported in pH units, was also referred to as "soil reaction" (Mason and Obenshain, 1939), and this term is occasionally still used in some publications. However, "soil reaction" is no longer used by soil chemists (SSSA, 2008). Because of the importance of acidity and alkalinity in soils, pH has been called a master variable (McBride, 1994), with knowledge of soil pH required to understand many chemical processes including ion mobility, precipitation and dissolution equilibria and kinetics, and oxidation–reduction equilibria. Soil pH also affects nutrient availability to plants and the negative response of many plant species to soil acidity.

Soils are a complex mixture of solid-phase components that react to yield a measured pH value. These components also buffer soils against pH changes caused by natural and anthropogenic inputs of acids and bases. Knowledge of the reactions that buffer soil pH is necessary for an understanding of natural soil weathering and the response of a soil to inputs of lime, acid-forming N fertilizers, acid-mine wastes, and acid rain. The discussion in

this chapter focuses on the reactions of components that buffer soil pH in upland soils. Factors affecting pH and buffering in flooded soils are discussed in Chapter 14.

19.2 Definition and Determination of Soil pH

Because pH is a term that is only defined for solutions, in a strict sense, it cannot be applied to a solid-phase material like soil. However, the chemical properties of the solid-phase components in soil define the pH of the soil solution, the water in soil pores (Chapter 12).

19.2.1 Definition of pH

The term pH was defined by Sorensen (1909) to provide a convenient way of representing the H$^+$ or OH$^-$ concentrations in aqueous solutions. As currently defined, pH is the negative logarithm, base 10, of H$^+$ activity, log (H$^+$), where activity is the concentration adjusted for nonideality caused by charge–charge interactions with other ions in solution. In all except saline soils, the ionic interaction correction is small and the difference between

H^+ concentration and activity is small. The determination of H^+ also provides a measurement of OH^- in solution. At 25°C in pure water, the relation between OH^- activity, (OH^-), and H^+ activity, (H^+), is given by

$$K_w = (H^+)(OH)^- = 1.0 \times 10^{-14} \qquad (19.1)$$

where K_w is the ionization constant for water. Expressing Equation 19.1 as negative logarithms yields

$$pH + pOH = 14 \qquad (19.2)$$

where pOH is the negative logarithm of the OH^- activity.

19.2.2 Determination of pH with Electrodes

Soil pH is determined by measuring the pH after equilibrating soil with pure water or a salt solution (SSSA, 2008). The pH of a solution in equilibrium with a soil varies with the composition and concentration of the salts in the solution because cations in solution displace H^+ and Al^{3+}, an acidic cation, from soil surfaces. Three common standard methods for determining pH in soils involve the suspension is distilled water, 0.01 M $CaCl_2$ or 1 M KCl solutions, and measurement of the solution pH in the solution (Thomas, 1996). In the United States, the most commonly reported pH measurements are in 1:1 (weight:volume) suspensions of air-dried soil in distilled water. A suspension of soil is prepared (e.g., 10 g of soil and 10 mL of distilled water), stirred vigorously, and then allowed to stand for 10 min. The suspension is stirred again and the pH is measured with a glass pH electrode and a pH meter (Thomas, 1996). The pH can also be measured with an ion-sensitive field-effect transistor (ISFET) electrode. These solid-state devices are more robust than glass electrodes, have a more rapid response, and are well adapted for making field measurements of soil pH (Rossel and Walter, 2004). However, the solid-state electrodes are more expensive than glass electrodes.

The determination of soil pH in a 1:1 water suspension is expected to give a higher pH value than the soil solution at field water contents. The quantity of water added results in a dilution of the salts in the soil solution and a lower-equilibrium salt concentration. This effect is illustrated by the 0.4 unit increase in pH obtained for an increase in water content in the soil suspension from 1:1 to 1:10 (Thomas, 1996). The 1:1 water determination of pH is influenced by the natural seasonal variation in soil solution salt concentrations and the effects of soil management; for example, recent fertilization. Soil pH measured in water is reported as $pH_{(H_2O)}$ or pH_w.

At low salt concentrations, an error due to the junction potential effect can occur in determination of $pH_{(H_2O)}$. A pH measurement requires contact with the solution by a glass electrode and a porous liquid junction of a reference electrode. This is necessary to complete the circuit between the pH-sensitive glass electrode and the reference electrode, which is often built in the same body as the glass electrode to form a combination electrode. The filling solution for the reference electrode is a concentrated KCl solution, which slowly leaks into the test solution through a porous liquid junction. Because soils are cation exchangers, they can have a disproportionate effect on the rate of K^+ diffusion compared to Cl^- diffusion into solution, which sets up a potential across the junction (Coleman et al., 1951). This can cause a reduction in the measured pH (Thomas, 1996).

The method for measurement of pH in 0.01 M $CaCl_2$ is the same as for measurement of pH in distilled water (Thomas, 1996). Because of the displacement of H^+ and Al^{3+} from soil materials by Ca^{2+}, pH in 0.01 M $CaCl_2$ [$pH_{(CaCl_2)}$] is on an average about 0.3–0.4 units lower than in water (Essington, 2004). The measurement of pH in 0.01 M $CaCl_2$ results in reduction or elimination of the problems due to variation in soil solution salt concentration and it eliminates the junction potential effect. Calcium is used in the determination of pH because it is the predominant soil solution cation in soils of temperate regions. The 0.01 M concentration, however, is somewhat higher than that found in most soil solutions.

The measurement of pH in 1 M KCl suspensions also generally yields lower pH values than in water. However, for some subsurface horizons of highly weathered soils of the tropics, pH in KCl can actually be greater than in water (van Raij and Peech, 1972). This occurs in subsoils low in permanent charge silicate clays and low in organic matter. Oxides and hydroxides of iron and aluminum are the predominant ion exchangers in these soils and at very acid pH values they are anion exchangers (Section 19.7). The addition of KCl results in a displacement of OH^- by Cl^- and an increase in pH (McBride, 1994).

19.2.3 Determination of Soil pH Using pH-Sensitive Dyes

Rapid determination of soil pH can be made colorimetrically with pH indicator dyes. Colorimetric methods are based on the change in color that takes place upon disassociation of a weak acid or a weak base organic dye. In solution, a weak acid dye molecule can dissociate:

$$HI = H^+ + I^-. \qquad (19.3)$$

An increase in pH will cause a change in color as the undissociated dye, HI, changes to the dissociated form, I^-. Typically a mixture of dyes is used to yield color changes that take place over a wide range of pH. A dye solution is mixed with soil to make a slurry, and the dye is decanted from the soil so the color can be compared with a color chart. The pH measured in this manner corresponds with $pH_{(H_2O)}$ measured with a glass electrode but is not as precise and can vary from the glass electrode results by as much as 0.4 units (Mason and Obenshain, 1939). Dye-impregnated pH papers also can be used to get quick pH measurement within 0.5 units of the true $pH_{(H_2O)}$ (Thomas, 1996).

19.3 Acids and Bases in Soil Solutions

Soil solutions contain a mixture of weak acids and weak bases that buffer the pH of the solution. This buffering is small compared to the quantity of acidity or basicity (alkalinity) associated with the solid phases in soil and has little impact on soil pH buffering. However, the acid and base components in soil solutions directly impact plant roots and soil microbes and thus directly influence the vitality of the biotic community in a soil. Also, the acids and bases in soil solution directly impact mineral weathering and biogeochemical reactions involved in soil genesis.

In this chapter, we will use Brønsted's definition of acids and bases where an acid is a hydrogen ion (H^+) donor and a base is an H^+ acceptor (Stumm and Morgan, 1996). Because an H^+ ion is just a proton, acids can be described as proton donors and bases as proton acceptors. According to this definition, reaction of an acid to lose a proton produces a conjugate base that can accept a proton; if the reaction is reversed. Conversely, a base that accepts a proton yields a conjugate acid. For example, when nitric acid donates protons to water, the base is H_2O. The reaction is

$$HNO_3 + H_2O = NO_3^- + H_3O^+. \quad (19.4)$$
The nitrate anion is the conjugate base of nitric acid and the hydronium ion, H_3O^+, is the conjugate acid of water. Nitric acid is a strong acid because at all except very high H^+ concentrations Reaction 19.4 goes all the way to the right and all of the HNO_3 is ionized. The conjugate base of nitric acid, the nitrate anion, is a very weak base because it has very little tendency to accept protons. The above reaction in aqueous solution is often abbreviated to

$$HNO_3 = NO_3^- + H^+. \quad (19.5)$$
19.3.1 Weak Acids

The weak acids in soil solutions include organic carboxylic acids, H_2CO_3, and Al^{3+}, a metal ion that undergoes hydrolysis. Carboxylic acids are organic compounds with one or more –COOH groups that have the potential to ionize to form the carboxylate anion, $RCOO^-$, according to the reaction

$$RCOOH = RCOO^- + H^+ \quad (19.6)$$
where
  RCOOH is any carboxylic acid
  R is an organic structure

Organic acids in soil solutions include simple acids like malic acid $(COOH)CH_2CH(OH)CH_2(COOH)$ and citric acid $(COOH)CH_2C(OH)(COOH)CH_2(COOH)$, which are exuded from plant roots or by soil microbes. These acids generally have a short lifetime in soils because they are easily consumed by soil microbes. In addition, soil solutions contain macromolecular humified components produced by degradation of plant debris that can be operationally separated into humic and fulvic acids

(Chapter 11; Stevenson, 1994), with fulvic acids predominating in soil solutions. These natural organic acids are complex mixtures that contain carboxylic acid groups.

The strength (ability to donate protons) of a carboxylic acid is defined by the equilibrium constant:

$$K_a = \frac{(RCOO^-)(H^+)}{RCOOH} \quad (19.7)$$

where K_a is the acidity constant. Stronger acids have greater acidity constants. Often, the strength of a weak acid is given in terms of the negative log of the K_a, the pK_a. The lower the pK_a the greater the strength of the acid. At the pH equal to the pK_a, an acid is half ionized. At higher pH, it is more than half ionized, while at lower pH it is less than half ionized. Thus, at solution pH values less than the pK_a, a weak acid has a greater ability to donate protons than at higher pH values. Carboxylic acids in soil solution have pK_a values generally in the range of 3–5.

The soluble fulvic acids also contain phenolic groups, ArOH, where Ar is an aromatic six-carbon ring structure. Phenolic groups are generally much less concentrated than the carboxyl groups and they are much less acidic having pK values ranging from 7 to 11.

The Al^{3+} ion can be an important weak acid component in soil solutions of highly acid soils. This ion contributes to soil solution acidity and causes the acid toxicity response experienced by many plants in acid soils (Bloom et al., 2005; Fageria and Baligar, 2008). In water, Al^{3+} undergoes a series of hydrolysis reactions, which produce protons (Nordstrom and May, 1996):

$$Al^{3+} + H_2O = AlOH^{2+} + H^+ \quad pK_{a1} = 5.00, \quad (19.8)$$

$$AlOH^{2+} + H_2O = Al(OH)_2^+ + H^+ \quad pK_{a2} = 5.1, \quad (19.9)$$

$$Al(OH)_2^+ + H_2O = Al(OH)_3^0 + H^+ \quad pK_{a3} = 6.7, \quad (19.10)$$

$$Al(OH)_3^0 + H_2O = Al(OH)_4^- + H^+ \quad pK_{a4} = 6.2. \quad (19.11)$$
Although the second, third, and fourth hydrolysis reactions are important in determining the chemistry of Al, only the first hydrolysis reaction is a major source of protons in soil solution. The low solubility of solid $Al(OH)_3$ limits the quantity of Al ions. At a pH of 5.0, a solution in equilibrium with $Al(OH)_3$ has a total concentration of Al^{3+} of less than 10^{-6} M (Nordstrom and May, 1996).

In soils, carbonic acid is also an important weak acid (H_2CO_3) that is created by the dissolution of carbon dioxide:

$$CO_{2(g)} + H_2O = H_2CO_3 \quad pK = 1.51 \text{ (Stumm and Morgan, 1996).} \quad (19.12)$$
When pH is increased, this acid ionizes to produce bicarbonate and H^+:

$$H_2CO_3 = HCO_3^- + H^+. \tag{19.13}$$
The pK_a for Reaction 19.13 is 6.35 (Stumm and Morgan, 1996) meaning that carbonic acid is a weaker acid than organic carboxylic acids or Al^{3+}. The concentrations of HCO^- in solution increase both with increase in pH and increase of concentration of CO_2 in the air of soil pores. At a pH value above 6, HCO_3^- is often the predominant anion in soil solution.

For solutions in equilibrium with the earth's atmosphere, H_2CO_3 is directly proportional to the partial pressure of atmospheric CO_2, which in 2007 was 3.83×10^{-4} atm. The concentration is increasing at the rate of 0.014×10^{-4} atm year^{-1} (Anon, 2008). However, in soils where root and microbial respiration are active, the partial pressure can easily be 100 times greater (Fernandez and Kosian, 1987; Magnusson, 1992). This has a great effect on the content of HCO_3^- in soils (Andrews and Schlesinger, 2001).

19.3.2 Weak Bases

All of the anions of the weak acids above, as well as the hydrolyzed Al cations, are weak bases that can accept protons in the pH range found in soils. Because of the low pK_a values for organic acids and $AlOH^{2+}$, these ions are only important proton acceptors in very acid soils. For most neutral and alkaline soils, the concentration of bicarbonate determines the alkalinity of soil solutions, where alkalinity is defined as the quantity of strong acid needed to lower the pH of a solution to the end point for complete protonation of bicarbonate (about pH = 4.8) (Stumm and Morgan, 1996). The carbonate ion, CO_3^{2-}, is significant only in very high pH soils because the pK_a for the ionization of HCO_3^- to CO_3^{2-} is 10.33 (Stumm and Morgan, 1996).

Under some conditions, solution ammonia, $NH_{3(aq)}$, is a significant base. These conditions are induced by the addition of fertilizer N as anhydrous ammonia $[NH_{3(g)}]$, or urea. When $NH_{3(g)}$ is injected into a soil, it reacts with the soil solution to lower the H^+ activity raising the pH. Ammonia is a conjugate base of NH_4^+ and if the reaction in water is written like the weak acid reactions above:

$$NH_4^+ = H^+ + NH_{3(aq)}. \tag{19.14}$$
The pK_a of this reaction is 9.5 (Stumm and Morgan, 1996) and in all except the highest pH soils, the reaction goes to the left consuming protons. This reaction creates localized pH values near anhydrous ammonia injection bands that can be >9.5 (Havlin et al., 2005).

Dissolution and hydrolysis of urea fertilizer in soils can also produce localized high concentrations of $NH_{3(aq)}$ that can result in localized high pH. Fertilizer granules hydrolyze readily due to the presence of urease enzymes in soils, resulting in an overall reaction:

$$\underset{\text{Urea}}{(NH_2)_2CO} + 2H_2O = HCO_3^- + NH_4^+ + NH_{3(aq)}. \tag{19.15}$$
The basicity effect of the NH_3-producing fertilizers is short-lived because biological oxidation of ammonium to nitrates produces two H^+ ions, and the net effect is acidification.

19.4 Overview of Reactions Controlling pH and pH Buffering

Reactions of the solid-phase components control soil pH and are the reactions that buffer soil pH against rapid pH change with natural or anthropomorphic inputs of acids and bases (Bloom et al., 2005). Solid-phase soil materials have a much greater capacity to accept or donate protons than the soluble acids and bases in soil solution. Magdoff and Bartlett (1985) investigated the buffering in 51 surface soils of Vermont, USA by reacting these soils with H_2SO_4 or $CaCO_3$ for 30 days and determining the final pH in 0.01 M $CaCl_2$. They found maximal buffering (minimal slope of pH vs. added acid or $CaCO_3$) to occur at both pH 3.5 or less and pH 7.5 or greater (Figure 19.1). The upper bound of the pH in the buffering shown in Figure 19.1 is fixed by the solubility of $CaCO_3$ (Magdoff and Bartlett, 1985). They also showed that the buffer plot was generally linear in the pH range of 4.5–6.5, a range that encompasses most acid agricultural soils.

The pH-buffering reactions in soils include proton desorption and adsorption reactions with mineral and organic components as well as ion exchange, dissolution, and precipitation. Some of the soil components are effective in buffering over a wide range of pH values, while others are effective over a limited pH range (Table 19.1). The buffer ranges in Table 19.1 are those that were developed by Bloom et al. (2005) and are somewhat similar to those shown
FIGURE 19.1 Titration of surface soils from Vermont, U.S.A, with H_2SO_4 and $CaCO_3$. The acid and base ($CaCO_3$) additions are reported per gram of soils. The pH_{CaCl_2} was measured after a 30-day reaction at field capacity moisture content. (From Magdoff, F.R., and R.J. Bartlett. 1985. Soil pH buffering revisited. Soil Sci. Soc. Am. J. 49:145–148. With permission of Soil Science Society of America.)

TABLE 19.1 Reactions of Solid-Phase Soil Components That Buffer pH in the Range of 3.5–9.5

pH Buffer Substance	pH Range	Proton Acceptor or Donation Reactions
Limestone, $CaCO_3$	7–9.5	Dissolution and precipitation
Oxides and hydroxides of Fe and Al; silicate clay edges	Whole pH range	H^+ adsorption and desorption on surface hydroxyl sites
H^+–SOM	Whole pH range	Dissociation and protonation of carboxyl and phenol groups
Al-SOM and $Al(OH)_{3(s)}$	5–8	Precipitation of organic bound Al^{3+} as $Al(OH)_3$ or dissolution of $Al(OH)_3$ by organic acids
Al^{3+}/H^+-exchange in SOM	Less than 4.5	H^+ exchange with Al^{3+} on carboxyl and phenol groups
$Al(OH)_3$	4–5.5	$Al(OH)_3$ dissolution/precipitation in soils with very low SOM content
Silicate clay interlayer $Al(OH)_n^{3-n}$ in 2:1 clays	4.2–7	Hydrolysis and precipitation or dissolution of interlayer $Al(OH)_3$
Permanent charge silicate clays	3.5–4.2	Ion exchange of H^+ and Al^{3+}
Irreversible dissolution of high-activity 2:1 silicate clays and poorly ordered aluminosilicates	Less than 3.5	Consumes H^+ upon release of Al^{3+} from reactive silicates
Very slow irreversible weathering primary silicate minerals	Whole pH range	Consumes H^+ upon dissolution of Ca^{2+}, Mg^{2+}, K^+, and Na^+ from primary minerals

by Ulrich (1991), with modifications and additions. For example, Ulrich did not include soil organic matter (SOM) and reactions on oxide and hydrous oxide surfaces. The buffer reactions in Table 19.1 will be discussed in more detail in Sections 19.5 through 19.9.

19.5 Buffering by Soil Organic Matter

Soil organic matter is a very important component of pH buffering in surface soils, even in typical upland soils that contain only a few percent organic matter. Like the soluble organic components in soil solution discussed in Section 19.3.1, SOM contains carboxyl and phenolic groups that can donate protons. Most of the acidity in SOM is contributed by the humidified components, operationally defined as humic and fulvic acid. In soils, some of the weak acid sites exchange protons with Al^{3+}, which alters the proton donation behavior of SOM. Based on chemical analysis of humic and fulvic acids extracted from SOM (Chapter 11) various organic acids have been proposed to represent the acidity of carboxyl and phenolic sites in SOM. Most of the acidity is thought to arise from carboxyl and OH groups bound to aromatic ring structures, which can be represented by benzoic acid (Ar–COOH, pK_a = 4.2) and phenol (Ar–OH, pK_a = 10.0), where Ar is an aromatic ring (Smith et al., 2004).

Soil organic matter buffers pH over a wider range of pH values than predicted by a simple mixture of benzoic acid and phenol. The titration plots for two humic acids with an alkali metal hydroxide shown in Figure 19.2 illustrates that maximum buffering (minimal slope) is in the pH range of 4–6. At very low pH, the plots in Figure 19.2 have very low slopes because of the effect of dilution of acid on H^+ concentration as presented on a log (pH) scale. And at pH > 8.5, the buffering due to phenolic groups contributes to the low slope. A broadening of the buffering response occurs because the aromatic ring structures of the humic acid and fulvic acids are polysubstituted with carboxyl –COOH and phenolic –OH. This shifts the pK_a values, resulting in aromatic ring structures with wide ranges of individual pK_a values. Also, with the ionization of the acid sites, negative charges accumulate on
FIGURE 19.2 Titration of 2 humic acids with strong base. (From Stevenson, F.J. 1994. Humus chemistry: Genesis, composition, reactions, 2nd Ed. Wiley, New York. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. With permission.)

macromolecular structures and this charge reduces the proton donation ability of humic and fulvic acids at high pH values (McBride, 1994). The ionization of carboxyl groups is generally complete at pH 8 and the ionization of phenolic groups is complete at pH 11. Thus, common methods for determination of carboxyl acidity involve titrating to pH 8; and for the determination of the phenol titration to pH in excess of 11 (Stevenson, 1994). The negative charge sites produced by the ionization of the weak acid sites on humic and fulvic acids bind exchangeable cations. Organic matter contributes much of the pH-dependent cation exchange capacity (CEC) to soils (Chapter 16).
FIGURE 19.3 Titration of Al-SOM containing different contents of Al^{3+}. (From Hargrove, W.L., and G.W. Thomas. 1982. Titration properties of Al-organic matter. Soil Sci. 134:216–225. With permission of Wolters Kluwer Health.)

The binding of Al to acid functional groups in SOM is important both for Al chemistry and for pH buffering. In acid mineral soils, many of the carboxylate sites in SOM are bound to Al^{3+}. This bonding is strong enough that only a small fraction of the Al can be extracted with 1 M KCl (Bloom et al., 1979), and most authors consider Al (and H^+) bound to SOM to be nonexchangeable (Bertsch and Bloom, 1996). This strongly bound Al has a large effect on buffering. Hargrove and Thomas (1982) titrated SOM with varying Al^{3+} contents and found that the pH buffering of the Al^{3+}-treated SOM occurred at higher pH than for H^+-saturated SOM (Figure 19.3). Aluminum-saturated SOM is a weaker acid than H^+-saturated SOM.

As the pH of Al-SOM is raised to greater than about 5, the Al^{3+} in solution exceeds the solubility of $Al(OH)_3$ and precipitation of amorphous $Al(OH)_3$ occurs (Walker et al., 1990). This can be illustrated by

$$2Al(RCOO)_3 + H_2O = 3RCOO^- + 3H^+ + Al(OH)_{3(s)}. \qquad (19.16)$$
This reaction is reversible and when the pH is lowered $Al(OH)_3$ dissolves and Al again becomes bound to organic matter. As with H^+-SOM, increasing of pH by adding a base increases surface charge and the organic matter becomes more saturated with the cation of the base. In humic materials, except at very low pH, the pH is positively correlated with the saturation of cation exchange sites with the Ca^{2+}, Mg^{2+}, Na^+, and K^+; all cations of strong bases. In soil science, these are called "base cations" and a base saturation (BS) value, which is positively correlated to pH, can be calculated as a sum of charges of base cations divided by the CEC:

$$BS = \frac{2Ca^{2+} + 2Mg^{2+} + Na^+ + K^+}{CEC}. \qquad (19.17)$$

In this calculation, the CEC value is determined at a reference pH of 7 or 8 (Bloom and Grigal, 1985; Ross et al., 2008). In less-acidic and neutral soils, the most abundant base cation is Ca^{2+}.

As soils are acidified, base cations are displaced and the BS value decreases. At pH values less than 5, the BS is low and protons can displace soil adsorbed Al^{3+} ions. This reaction results in a decrease in pH without a decrease in BS because H^+-saturated SOM is a stronger acid than Al-saturated SOM. At pH less than 4.5, this exchange can add very significant quantities of Al^{3+} to soil solution. At these low pH values, where hydrolysis of Al^{3+} is not very significant Al^{3+} is acting more like a base cation. In the high acid A and O horizons typical of many forest soils of northern temperate and humid tropical regions, plots of BS vs. pH show a better positive correlation with BS when Al^{3+} is included as a base cation than if it is included as an acid cation (Skyllberg, 1994, 1999; Ross et al., 2008).

SOM provides much of the pH buffering in most surface soils and much of the CEC. Helling et al. (1964) estimated the mean CEC of SOM in 60 mineral soils of Wisconsin, USA, at pH 8, to be 2000 mmol$_c$ kg^{-1} of SOM. This value is the equivalent to the value for the titration of the acid form of organic matter with $Ca(OH)_2$ to pH 8 and provides a reasonable estimate for the capacity of SOM in mineral soils to buffer pH in the range of 3–8. With the exception of $CaCO_3$, the pH-buffering capacity of SOM is equal or greater than other components in the soil (Table 19.2). Another indication of the importance of SOM for buffering in soils is the results after adding H_2SO_4 and $CaCO_3$ to 51 surface soils (Magdoff and Bartlett, 1985). They took the data, including the four soils in Figure 19.1, and replotted it normalized to equivalent SOM contents. This yielded a single plot (Figure 19.4) for soils of differing organic matter contents suggesting that in these northern temperate region surface soils, the pH buffering is a function mostly of organic matter content.

TABLE 19.2 Approximate Maximum Proton Donation or Adsorption Capacity of Soil Materials in the pH Range of 3.5–8

Soil Material	Capacity, mmol kg^{-1}	References
Silicate clays		
Smectites	800–1,500	McBride (1994)
Vermiculite	1,500–2,000	McBride (1994)
Illite	200–400	McBride (1994)
Kaolinite	10–50	Thomas and Hargrove (1984)
SOM	2,000	Helling et al. (1964)

[b] The precipitation and dissolution of $CaCO_3$ takes place at pH 7 or greater.
FIGURE 19.4 pH_{CaCl2} after a 30-day reaction of 51 soils from Vermont, U.S.A, with varying additions of H_2SO_4 and $CaCO_3$. The acid and base addition are reported per gram of SOM. The data for all of the soils were adjusted along the x-axis to coincide with the zero addition pH for soil 51 (see Figure 19.1). (From Magdoff, F.R., and R.J. Bartlett. 1985. Soil pH buffering revisited. Soil Sci. Soc. Am. J. 49:145–148. With permission of Soil Science Society of America.)

19.6 Proton and Al Exchange in Silicate Clays

Ion exchange reactions on permanent charge sites in silicate clays can contribute to pH buffering (for a detailed discussion of ion exchange in clays see Chapter 16). The pH buffering by permanent charge on clays can involve exchange of hydronium ions, H_3O^+, but the exchange of Al^{3+} is much more significant.

High-activity clays; smectites, vermiculites, and illites, when saturated with H^+ have very low pH values and are not stable. When montmorillonite, a smectite, is saturated with H^+ the pH is less than 3.5. After 24 h of aging, acid dissolution of the clay structure produces Al^{3+} ions resulting in an increase in pH and replacement of the exchangeable H^+ ions with Al^{3+} (Coleman and Craig, 1961). Aluminum clays are proton donors because of the ability of Al^{3+} on clay exchange sites to hydrolyze and to precipitate as $Al(OH)_3$, but they are weaker proton donors than H^+ clays. Extraction of acid soils with neutral salt solutions, for example, 1 M KCl, yields mostly Al^{3+} not H^+ (Thomas and Hargrove, 1984).

Titration of Al^{3+} montmorillonite (Figure 19.5) shows that at $pH_{(H_2O)}$ values in the range of 5–6, the Al^{3+} on permanent charge sites strongly buffers pH (Turner and Nichol, 1962). Data in Figure 19.5 also show that as in soil, the measured pH in $CaCl_2$ is lower than the pH in water.

When base is added to an Al^{3+}-saturated smectite or vermiculite, the initial reaction is the hydrolysis of Al cations on exchange sites (Bloom et al., 1977), but with sufficient addition of strong base, the Al^{3+} will eventually precipitate as $Al(OH)_3$ in the interlayer space in the clay, accounting for much of the clay-mediated buffering at pH > 5. Because of OH^- deficiencies in interlayer $Al(OH)_3$, the interlayer can neutralize the negative charge on the clay. In the case of smectite, this produces hydroxy interlayer
FIGURE 19.5 Titration of an Al saturated montmorillonitic clay with NaOH with and with without the addition 0.001 M $CaCl_2$. (From Turner, R.C., and W.E. Nichol. 1962. A study of the lime potential: 2. Relation between the lime potential and percent base saturation of negatively charged clays in aqueous salt suspensions. Soil Sci. 94:58–63. With permission of Wolters Kluwer Health.)

smectite (HIS), and in the case of vermiculite, this produces hydroxy interlayer vermiculite (HIV) (Chapter 21). Because the precipitation of interlayer $Al(OH)_3$ blocks Al^{3+} in the interlayer from reacting with the base, the titration end point in Figure 19.5 is less than the CEC of the clay, which is 800 $mmol_c$ kg^{-1}.

As with SOM, buffering in Al^{3+}-saturated clays can be described as function of BS, assuming that both H^+ and Al^{3+} acid cations and that Al^{3+} cations represent 3 mol of acidity per mole of Al^{3+}. This is a usable generalization at pH values high enough for Al^{3+} to hydrolyze and act like an acid cation. In contrast, studies of very acidic surface soils from northern temperate forests have shown that at pH values less than 4.5, Al^{3+} should be treated as a base cation (Skyllberg, 1994; Ross et al., 2008).

The capacity of silicate clays to buffer pH varies widely because of the large difference in the CEC of clays (Table 19.2). Kaolinite, a low-activity clay, has little or no permanent charge and has little capacity to buffer pH (Chapter 21). Illite has a much greater CEC and is a much more effective buffer of pH. Smectites and vermiculites are even more effective in buffering pH. Among the silicate clays, only the highest charge vermiculites approach the buffer capacity of SOM.

19.7 pH-Dependent Charge Buffering by Mineral Components

Like SOM, oxides and hydroxides of Fe(III) and Al, and poorly crystalline aluminosilicates, contribute to the pH-dependent charges in soil and to pH buffering. In addition, the edges of

crystalline silicate clays make a minor contribution to pH-dependent charge (Chapter 16.) Unlike SOM, these materials have surfaces that are both proton donors and proton acceptors.

19.7.1 Oxides and Hydroxides of Iron and Aluminum

The oxides and hydroxides of Fe(III) and Al that accumulate in response to weathering are particularly important for pH buffering highly weathered soils (Uehara and Gillman, 1982). Common iron minerals in soil include hematite (α-Fe_2O_3), goethite (α-FeOOH), and ferrihydrite ($Fe_5O_7 \cdot 4H_2O$) (Chapter 22). By far the most common aluminum hydroxide mineral is gibbsite, $Al(OH)_3$. In water, the hydrated surfaces of these oxides and hydroxides contain strongly bound OH groups that can act both as proton donors and proton acceptors. For hematite, the surface hydration reaction is

$$\text{Surface } Fe_2O_3 + 3H_2O = \text{Surface } 2Fe(OH)_3. \qquad (19.18)$$
The strong bonding of the O atom to Fe(III) and Al weakens the bond of the proton to the O atom, making the surface-OH groups weakly acidic and at high pH, the metal-bound hydroxide groups can donate proton creating negative surface charges (McBride, 1994):

$$\text{Surface FeOH} = \text{Surface FeO}^- + H^+. \qquad (19.19)$$

This reaction can also be written as an adsorption of OH^-:

$$\text{Surface FeOH} + OH^- = \text{Surface FeO}^- + H_2O. \qquad (19.20)$$
Also these surface-OH groups can accept protons at low pH to become positively charged:

$$\text{Surface FeOH} + H^+ = \text{Surface FeOH}_2^+. \qquad (19.21)$$
Surface adsorption of H^+ and OH^- is quantified by titrating oxide suspensions in Na^+ or K^+ salts of anions that do strongly adsorb to the oxide surfaces (e.g., NO_3^-). The data of Parks and de Bruyn (1962) illustrate typical titrations for oxide suspensions (Figure 19.6). These data show the effects of increasing KNO_3 concentration on the quantity of H^+ or OH^- adsorbed. McBride (1994) explains this effect, in a KNO_3 solution, as due to K^+ displacement of H^+ at high pH and the NO_3^- displacement of OH^- at low pH. At pH values less than 7, the oxides and hydroxides of Al and Fe are positively charged, and these surfaces are anion exchangers while at pH greater than 9 they are cation exchangers. At pH values in the range of 7–9, a point is found where the concentration of salt in solution has no effect on the pH. This is the point at which the net charge on the surface is zero; the point of zero net charge (pznc, also called the point of zero salt effect). For oxides and hydroxides of iron and aluminum, almost all measured pznc values are in the range of 7–9 (Chapter 15), meaning that
FIGURE 19.6 Titration of Fe_2O_3 with KOH and HNO_3 in suspensions containing different concentrations of KNO_3. (With permission from Parks, G.A., and P.D. de Bruyn. 1962. The zero point of charge of oxides. J. Phys. Chem. 66:967–963. Copyright 1962 American Chemical Society.)

unlike silicate clays and organic matter the net surface charge of these materials is positive in all except alkaline pH soils.

19.7.2 pH-Dependent Charges on Silicate Clay Edges

The layer structure of silicate clays includes an AlOH layer with exposed hydroxyl groups on the edges of the structure (McBride, 1994). These Al hydroxyl groups can adsorb or desorb protons, but because of the influence of the Si^{4+} ions in the structure, the pznc is lower than for gibbsite. For example, a reported value for the pznc for the edge of kaolinite is 2.9 (Chapter 15). This means the edge charge can contribute to the negative charge in soils. For high-charged clays like smectites and vermiculite, this edge charge is small compared to the permanent structural charge. For example, for a smectite at pH 8, the pH-dependent negative charge is about 50 mmol$_c$ kg^{-1} compared to a permanent charge of about 750 mmol$_c$ kg^{-1} (McBride, 1994).

19.7.3 Imogolite and Allophane

Allophane and imogolite are aluminosilicates that like silicate clay edges have pH-dependent charge surfaces. Allophane is noncrystalline, not having long-range ordering in the structure,

and imogolite, which forms long tubes (Chapter 23; Wada, 1989) is a paracrystalline mineral with some disorder in the structure. Both of these materials are found in abundance in young volcanic soils. They are also found in some young soils in glacial parent material (e.g., spodosols in northern forests). Imogolite and allophane have pznc values in the range of 5.5–7 (Clark and McBride, 1984; Wada, 1980).

19.8 Buffering by Dissolution and Precipitation of Carbonates

Carbonates are very important for pH buffering in nonacid soils. Calcite, $CaCO_3$, and dolomite, $CaMg(CO_3)_2$, are common components of soil parent materials in many soils. With sufficient rainfall and good drainage, these minerals weather from soils. In arid regions and in some areas in humid regions with poor drainage, however, $CaCO_3$ can accumulate in soils (Chapter 30; Doner and Lynn, 1989). Under some conditions in arid regions, $MgCO_3$, which is much more soluble than calcite, can accumulate. Calcite acts as proton acceptor according to

$$CaCO_3 + 2H^+ = Ca^{2+} + H_2O + CO_2$$

$$\log K = 9.73 \quad \text{(Stumm and Morgan, 1996)}. \quad (19.22)$$
The equilibrium equation for this reaction is

$$K = (Ca^{2+})\frac{(P_{CO_2})}{(H^+)_2}. \quad (19.23)$$

Calculation of this equilibrium requires knowledge of the CO_2 content in the soil atmosphere, expressed in units of partial pressure (P). At 1 atm total pressure, the value of partial pressure is equivalent to the volume fraction in the air. This equilibrium, rewritten in a form that shows how $CaCO_3$ weathers from calcareous soils, is

$$CaCO_3 + H_2CO_3 = Ca^{2+} + 2HCO_3^- \quad \log K = -7.42. \quad (19.24)$$

In soils, the CO_2 produced by soil microbial and root respiration dissolves $CaCO_3$ to produce calcium bicarbonate and over time $CaCO_3$ will weather out of well-drained soils.

The pH in soils that contain calcite varies widely. In a $CaCO_3$ suspension in distilled water in equilibrium with the ambient atmosphere ($P_{CO_2} \approx 3.8 \times 10^{-4}$ atm) will contain two bicarbonate ions in solution for every Ca^{2+} ion and the pH will be 8.3 (Stumm and Morgan, 1996). Because the P_{CO_2} in soils is greatly increased due to microbial and root respiration, soil solution in equilibrium with calcite will have pH values considerably lower than 8.3 (Inskeep and Bloom, 1986). The effect of P_{CO_2} on soil pH varies due to differences in the rate of soil respiration and the rate of gas exchange with the atmosphere. Gas exchange varies with depth and quantity of air-filled pores in a soil, and P_{CO_2} increases with depth and after rainfall fills soil pores with water (Flechard et al., 2007).

Inskeep and Bloom (1986) showed that in pots with growing soybean plants the P_{CO_2} ranged from 0.0006 atm in drier soils to 0.031 atm at moisture contents approaching saturation. By the principle of Le Chatelier (the mass action principle), Reaction 19.22 will be shifted to the left when P_{CO_2} is raised, resulting in an increase in (H^+) and a decrease in pH.

In soils, bicarbonate concentrations are commonly not equal to twice the concentration of Ca^{2+} because there can be other sources of HCO_3^- and Ca^{2+} than dissolution of calcite by carbonic acid. When the chemistry of a calcareous soil is dominated by calcium salts other than bicarbonate, $2[Ca^{2+}]$ can be much greater than $[HCO_3^-]$ and pH is much less than 8.3, even at low P_{CO_2}. Thus, calcareous soils containing gypsum ($CaSO_4 \cdot 2H_2O$), where $[Ca^{2+}]$ is elevated by gypsum solubility, pH can be as low as 7.0. In some arid regions, input of Mg^{2+}, Na^+, and HCO_3^- results in concentrations of HCO_3^- much greater than twice $[Ca^{2+}]$ and calcareous soils can have pH values as high as 9.5. In arid regions, where Mg accumulates, and hydrated $MgCO_3$ forms, pH is greater than 8.5 because magnesium carbonate is much more soluble than $CaCO_3$.

Calcareous soils are very strongly buffered against acidification. One kilogram of $CaCO_3$ can neutralize 20,000 mmol of H^+ and hold pH at a value greater than 7 until all of $CaCO_3$ is dissolved. Thus, $CaCO_3$ is a much more effective buffer than SOM or any other component in soil (Table 19.2). If $CaCO_3$ is compared with SOM on the basis of buffering against a decrease in pH from 8.0 to 7.0, the difference is even greater than shown in Table 19.2. This pH drop would result in the total dissolution of $CaCO_3$ but would only neutralize about 200 mmol$_c$ kg^{-1} of SOM, about one-tenth of the total buffer capacity of SOM. Because of the high buffer capacity of the $CaCO_3$, calcareous soils are considered to be unaffected by acid rain and it is generally considered impractical to artificially lower the pH of calcareous soils to allow for the growth of acid-loving plants.

19.9 H$^+$ Consumption by Irreversible Weathering of Aluminous Minerals

The buffering reactions discussed above are all reversible and can to some degree be described using equilibrium equations. Some reactions that consume H^+ in soils, however, are irreversible. These reactions include the weathering of primary aluminosilicate minerals and the destruction of high-activity clays in very low pH soils.

19.9.1 Weathering of Primary Silicates

Over the very long term, the weathering of primary aluminosilicate minerals from soil parent material consumes protons (Chapter 20). These reactions are irreversible for most primary minerals because these minerals only form at the high temperatures involved in rock-forming processes. An example of the weathering of a primary mineral is the reaction of the feldspar

anorthite to form kaolinite in acid soils. This reaction consumes two protons for every mole of calcium mobilized:

$$\underset{\text{anorthite}}{CaAlSiO_8} + H_2O + 2H^+ \rightarrow \tfrac{1}{2}\underset{\text{kaolinite}}{Al_2Si_2O_5(OH)_4} + Ca^{2+}. \quad (19.25)$$
The rates of weathering reactions depend on the type of primary mineral and the surface area exposed to soil solutions (Bloom and Nater, 1991). This means that, per unit mass, silt-sized particles weather much more rapidly than sand-sized particles. The rates of aluminosilicate dissolution reactions are pH dependent and at pH values typical in soils, aluminosilicates dissolve more rapidly at lower pH (Bloom and Nater, 1991; Sposito, 2004). Over time periods of less than decades, weathering of primary silicate minerals is generally not significant in buffering pH.

19.9.2 H⁺ Consumption by the Destruction of High-Activity Clay

When the $pH_{(H_2O)}$ of a soil is decreased to values less than about 3.5, high-activity clays can dissolve quite rapidly consuming protons and releasing Al^{3+} into solution. As discussed in Section 19.6, H⁺-saturated high-activity clays have pH values less than 3.5 and dissolve to release Al^{3+}. At this pH, $Al(OH)_3$ is too soluble to form in soils and kaolinite forms slowly, so high-activity clays tend to dissolve congruently (no solid phase is formed in the reaction). For a Ca^{2+} montmorillonite

$$Ca_{0.167}(Al_{1.67}Mg_{0.333})Si_4O_{10}(OH)_2 + 6H^+ + 4H_2O$$

$$\rightarrow 0.167Ca^{2+} + 0.167Mg^{2+} + 1.67Al^{3+} + 4Si(OH)_4 \quad (19.26)$$
where five of the six protons consumed are due to the release of Al^{3+} from the structure of the clay. This reaction likely accounts for much of the very strong buffering at pH 3.5 that was observed by Magdoff and Bartlett (1985) when they added H_2SO_4 to soils (Figures 19.1 and 19.3).

19.10 Determination of Buffer Capacities

The determination of the capacity of soils to buffer pH has long been an interest of soil chemists. Many crops respond positively to the addition of lime to acid soils, but because of the differences in buffer capacity, soils of similar pH may require vastly different quantities of lime to yield the same increase in pH. Horticulturists have also been concerned with decreasing the pH of nonacid soils and they use aluminum sulfate or elemental S to allow for the vigorous growth of acidophilic plants (e.g., azaleas, rhododendron, and blueberries). As with liming, the quantity of acidifying agent necessary to lower the pH of a soil by a given amount depends on the buffer capacity. Also, acid rain can negatively impact poorly buffered forest soils and the acidifying effects depend on the capacity of soils to buffer the long-term input of very dilute HNO_3 and H_2SO_4 (Bloom and Grigal, 1985; Ulrich, 1991; Watmough and Dillon, 2004).

19.10.1 Total Titratable Acidity

The total acidity in acid soils is operationally defined as consisting of two components, salt-replaceable (exchangeable) and residual (nonexchangeable) acidity (SSSA, 2008). Salt-replaceable acidity is the H⁺ and Al^{3+} extractable with 1 M KCl, while the residual acidity is the acidity that is titratable in a soil suspension but is not easily replaceable with KCl (Bertsch and Bloom, 1996). In practice, the residual acidity is determined by the difference between the total acidity neutralized by raising the pH of a soil to a reference pH, usually 7.0 or 8.0, and the salt-replaceable acidity.

Total acidity can be determined by the titration of a soil suspension in a salt solution to the reference pH using a strong base or by the addition of increments of $CaCO_3$ as shown in Figure 19.1. This produces a plot of the pH vs. the quantity of base consumed, but the response to titration with strong base and to $CaCO_3$ additions is slow, and other laboratory methods are usually used. A standard method for relatively rapid determination of total acidity is to react a soil for several hours or overnight with a solution containing 0.5 M $BaCl_2$ plus a triethanolamine (TEA) buffer adjusted to pH 8.0 or 8.2 (Thomas, 1982). TEA is well buffered at pH 8 and the solution contains Ba^{2+} to displace acidity from soil components. A reference pH of 8.0 or 8.2 is used to represent the pH attained when a soil is limed with excess lime. From a more fundamental point of view, pH 8 is a good choice because this is the end point for the titration of organic carboxyl acidity, as well as the Al^{3+} acidity bound to clays. With the $BaCl_2$–TEA method, the total acidity is calculated as the difference in the quantity of H⁺ needed to titrate the $BaCl_2$–TEA solution to a pH of about 5, using a pH indicator dye, before and after reaction with a soil. This difference represents the quantity of acidity that reacts with the TEA buffer.

An alternative method for the calculation of total acidity is the difference between the CEC determined at pH 7.0 with ammonium acetate and the sum of exchangeable bases. Determination of CEC at pH 7.0 is the method most often used in the classification of soils (Burt, 2004). In this method, soil is reacted with an ammonium acetate solution at pH 7.0, the excess ammonium acetate is leached from the soil, and the NH_4^+ ions bound to cation exchange sites are extracted with a salt solution and quantified (Sumner and Miller, 1996; Burt, 2004). Subtraction of the exchangeable bases from the pH 7.0 CEC represents the total acidity referenced to pH 7.0.

19.10.2 Lime Requirement

Development of the recommendations to growers for the liming of an acid soil with ground calcitic or dolomitic limestone (agricultural lime) requires a quick and easy method for the

determination of the quantity of base needed to raise the soil pH to an optimum value for a given crop (Bloom et al., 2005; Fageria and Baligar, 2008). Because crops differ in sensitivity to soil acidity, recommendations for liming may differ with crop. The most common methods used in the United States involve the reaction of a mixed buffer solution with a soil and after a period of reaction, measurement of the equilibrium pH (Godsey et al., 2007). The commonly used Mehlich method uses a mixed buffer solution containing acetate, glycerophosphate and TEA, in $BaCl_2$, that provides for a linear buffer response to acidity at pH values ranging from 4 to 6.5 (Mehlich, 1976; Hoskins and Erich, 2008). This solution has been modified by replacing the Ba with Ca to avoid the use of toxic substances (Godsey et al., 2007; Hoskins and Erich, 2008). The pH of the buffer mixture is adjusted to 6.5 and the lime requirement is determined from the pH after reaction with a soil using regression equations for different target pH values. At lower equilibrium pH, the lime requirement is greater. The regression equations are developed using the pH response of acid soils to known additions of $CaCO_3$ (Hoskins and Erich, 2008). Hoskins and Erich (2008) showed that the inclusion of a soil $pH_{(H_2O)}$ term increased the correlation coefficient of the regression. The Shoemaker–McLean–Pratt (SMP) mixed buffer method is also commonly used (McLean et al., 1977), but this method is decreasing in acceptance because it contains two toxic buffers, *p*-nitrophenol and chromate, and tends to cause plugging of liquid junctions of pH electrodes (Hoskins and Erich, 2008). Other mixed buffer methods for determination of lime requirement include those of Adams and Evans (1962), Woodruff (1948), and Nômmik (1983).

In areas of the world where highly weathered soils are dominant, it is common to base lime recommendations on the reduction of Al^{3+} saturation of the effective CEC, calculated as the sum of bases plus 1 M KCl extractable acidity (Fageria and Baligar, 2008). When lime is added, Al^{3+} precipitates to form insoluble $Al(OH)_3$, decreasing Al^{3+} toxicity. To determine the lime requirement, the 1 M KCl replaceable Al^{3+} acidity is calculated as three times the molar quantity of extracted Al and this acidity, expressed in units of $cmol_c$ kg^{-1}, is multiplied by a factor to calculate the lime requirement in Mg ha^{-1}. The factor varies from 1, or less, in sandy soils to greater than 3 in very clayey soils. Also an adjustment for exchangeable Ca^{2+} and Mg^{2+} is used to yield a lime requirement, even for low acidity soils, if a soil is low in Ca and Mg. These two ions are often deficient for plant growth in highly weathered soils (Fageria and Baligar, 2008).

19.10.3 Calcium Carbonate Concentrations in Soil

The quantity of calcium carbonate in soils is generally determined by methods that measure the CO_2 evolved after adding acid or the weight loss due to CO_2 loss. In the weight loss method, carefully weighed soil samples are added to weighed flasks containing 3 M HCl and loosely covered with a rubber stopper (Loeppert and Suarez, 1996). The flask is swirled and uncovered periodically until all of the CO_2 is evolved and the

flask is carefully reweighed. The content of carbonate is calculated assuming all of the carbonate is $CaCO_3$ with a formula weight of 100 g mol^{-1}. For soils that have less than 2% or 3% carbonate, the weight loss method is not accurate (U.S. Salinity Laboratory Staff, 1954; Loeppert and Suarez, 1996).

Determination of the evolved CO_2 provides a more accurate and precise measure of calcium carbonate (Loeppert and Suarez, 1996). Commonly used methods involve the determination of the pressure increase in a closed cell using an Hg manometer or pressure transducer CO_2 (Williams, 1949; Martin and Reeve, 1955; Skinner et al., 1959; Evangelou et al., 1984) or the gravimetric determination of CO_2 collected in a magnesium perchlorate trap (Loeppert and Suarez, 1996).

19.10.4 Determination of the Buffering of H+ Inputs in Noncalcareous Soils

Routine laboratory methods have not been developed for the determination of the capacity of soils to buffer against acidification. However, addition of increments of acid with long-term incubation, as used by Magdoff and Bartlett (1985), can be used to determine the response of soils to acid additions (Figures 19.1 and 19.4). An alternative method is to equilibrate soil suspensions repeatedly with dilute acid. Bloom and Grigal (1985) suspended soils in 2.5×10^{-4} M H_2SO_4 for 24 h decanted and repeated 13 times. By measuring the pH of the equilibrated solutions, they were able to determine the quantity of protons adsorbed due to pH buffering in the soil. They were also able to determine the Al^{3+} and base cation losses in each treatment. This method much more closely simulates the response to acidic deposition (acid rain) with the resultant loss of bases and Al^{3+}. Bloom and Grigal (1985) used their plots of pH response to acid to test a numerical model for the response of soils to acidic deposition.

19.11 Soil Acidification

Soil acidification occurs as a natural process during soil formation. With sufficient inputs of acid rain to poorly buffered soils, natural acidification can be very significantly accelerated (Bloom and Grigal, 1985; Ulrich, 1991). Much more rapid acidification is produced by the addition of ammonium-forming nitrogen fertilizers. Even more rapid acidification is produced by the oxidation of sulfur and sulfur compounds added to soils or of sulfur compounds deposited by natural processes in coastal wetland soils that are exposed to oxidation when the water table is lowered by artificial drainage.

19.11.1 Natural Acidification

Under conditions of good drainage and rainfall sufficient to produce leaching, H_2CO_3 and soluble organic acids cause the very slow acidification of soils that occurs during natural soil weathering. At pH values of about 6 and greater, the donation of protons by the reaction of H_2CO_3 to produce HCO_3^- (Reaction 19.13) is the predominant acidifying reaction. As the pH is

decreased to values much lower than the pK_a (6.35), H_2CO_3 is a less effective proton donor and organic acids, having lower pK_a values, are the predominant proton donors. In calcareous soils, $CaCO_3$ dissolution buffers the pH at values greater than 7 until it is all leached from the soil.

19.11.2 Acid Rain

The dry aerosol and wet acid deposition that makes up what is popularly called acid rain contains sulfuric and nitric acid plus NH_4^+ that can be oxidized in soil to produce nitric acid (Sparks, 2003). Under preindustrial conditions, these acids were of minor importance in determining the composition of soil solutions. Industrialization has resulted in elevated strong-acid acidity in rainfall, which can have long-term negative impacts on poorly buffered soils in forests and other natural areas (Bloom and Grigal, 1985; Ulrich, 1991). Since the concentration of acidic components of acidic deposition is small compared to soil buffering, even in poorly buffered soils, soil acidification is difficult to document by field-based observations and contradictory results have been reported (Courchesne et al., 2005). One of the major difficulties is the spatial variability in soil properties (Likens et al., 1998). Studies that have shown significant soil acidification that appears to be due to acid rain include the work of Courchesne et al. (2005), who reported a statistically significant decrease in pH in the humus layer of soil collected from 1993 to 2002 and Watmough and Dillon (2004), who reported a depletion of exchangeable Ca for soil collected from 1983 to 1999. Both of these studies were conducted in forests of eastern Canada.

19.11.3 Acid-Producing Fertilizers

Nitrogen fertilizers that produce NH_4^+ in soils; ammonium sulfate, ammonium nitrate, anhydrous ammonia, and urea, acidify soils. In soil, bacteria oxidize NH_4^+ to nitrate producing H^+ (Chapter 23; Havlin et al., 2005):

$$NH_4^+ + O_2 \rightarrow NO_4^- + 2H^+ + 2H_2O. \tag{19.27}$$
This reaction can produce sufficient acidification to require periodic addition of lime to cropland (Adams, 1984).

19.11.4 Acidification by Sulfur Compounds

Sulfuric acid produced in acid mine wastes or when the soils of coastal swamps are drained, can have a large impact on soils. When pyrite or iron sulfide associated with a seam of coal or a coastal organic soil is exposed to air, bacterial oxidation results in the production of sulfuric acid (McElnea et al., 2002; Sparks, 2003):

$$\underset{\text{pyrite}}{FeS_2} + {}^{15}\!/_{4}O_2 + {}^{7}\!/_{2}H_2O = Fe(OH)_3 + 2H_2SO_4. \tag{19.28}$$
Under these conditions, soil pH values of less than 3 are possible. This reaction has produced large areas of acid sulfate soils in Vietnam, Malaysia, and Indonesia (Sanchez, 1976).

Acidification of nonacid soils for the growth of acid-loving (acidophilic) plants can be accomplished using elemental S. Bacterial oxidation produces a similar effect as for the oxidation of pyrite (Slaton, 2001):

$$S + {}^{3}\!/_{2}O_2 + H_2O = H_2SO_4. \tag{19.29}$$

Growers using elemental S must be very careful because pH values of 3.5 are easily attainable when excess sulfur produces too much sulfuric acid (Leitzke and Peterson, 1987) (Figure 19.4).

An alternative method is to add aluminum sulfate, $Al_2(SO_4)_3$, which produces acidity according to the reaction:

$$Al_2(SO_4)_3 + 6H_2O = 2Al(OH)_3 + 3H_2SO_4. \tag{19.30}$$
The lower pH generated by aluminum sulfate is limited by the solubility of $Al(OH)_3$ and pH will not be decreased below about 4.5 but excessive aluminum sulfate can induce Al^{3+} toxicity problems for plant growth (Leitzke and Peterson, 1987).

Soil Mineralogy

Joseph W. Stucki
University of Illinois

FUNDAMENTAL TO THE EXISTENCE of soil is its inorganic mineral fraction. Indeed, of all soil constituents only this one is required. Without it, soil ceases to be soil. Organic matter, bacteria, and fertilizer chemicals greatly enhance various properties of the soil, but without the inorganic minerals, it is reduced to a soilless medium incapable of the diverse range of functions that are often taken for granted. A correct and complete understanding of the soil requires, therefore, an understanding of soil mineralogy.

A common misconception is that soil minerals are rather inert, unchanging, and nonlabile. The chapters in this part quickly dispel this view by painting a very different picture. They will show that the soil minerals are not only diverse in their origins, structures, and chemistry, but they provide the backbone for active chemical surfaces where many reactions are catalyzed and basic behaviors of the soil are born and changed. As described here and elsewhere in this book, these active surfaces

of the so-called inert fraction react with organic matter, invoking mutual alterations in the behavior of both the minerals and the organic matter. Life-sustaining liquid water is held at their surfaces and in their interstitial pores, and even retained in the liquid state at very low temperatures to preserve plant life during hard winter months. Oxidation–reduction reactions alter the chemical and physical properties of the constituent Fe- and Mn-bearing minerals, thus creating real-time transformations that are critical to many soil processes. Soil minerals come in a wide range of particle sizes and morphologies, which add texture and body to the soil, and vary in their degree of crystallinity. Their colors are also diverse, ranging from intense reddish brown to very light gray, or even green, yellow, or blue. They are dynamic in their properties, constantly changing with climate, time, and other environmental conditions. Some changes are rapid; others, slow. These attributes bring the soil to life, as it were, and create the framework within which the plant and

animal kingdoms spring forth and are sustained through every season and in every clime.

Minerals, the heart of the soil, are a dynamic and essential resource, classified according to their properties. Presented in the following chapters are descriptions of how minerals are formed and transformed. Specifics are given regarding the properties and behavior of the phyllosilicates, the plate-shaped minerals; iron, aluminum, and other (oxyhydr)oxides, which represent the more highly weathered mineral constituents; and amorphous minerals, which display active chemical properties but lack high order in their crystals. These are among the most important of the soil minerals. As such, knowledge of their characteristics will provide the basis from which a more complete understanding of soil physical and chemical properties may be acquired.

Alteration, Formation, and Occurrence of Minerals in Soils

G. Jock Churchman
University of Adelaide

David J. Lowe
University of Waikato

20.1 Introduction

This chapter, like Churchman (2000), seeks to bring readers up to date with information and understanding about the alteration of minerals and the nature of their products in the context of the formation and development of soils. It complements the articles by Bergaya et al. (2006), and recent books by Velde and Meunier (2008) and Velde and Barré (2010). This current chapter differs from Churchman (2000) in that it discusses the manner in which minerals, and especially secondary minerals, actually occur in soils, that is, it deals (in Section 20.3) with the occurrence, as well as the alteration and formation, of minerals in soils.

Secondary minerals are the most reactive inorganic materials in soils. Furthermore, they occur commonly in association with the most reactive organic materials in soils. It has often been inferred that knowledge of the properties of these reactive materials should enable close predictions of the useful soil properties, whether for growing plants, for filtering and partitioning water flow, for immobilizing contaminants, for supporting human-made structures, or for other purposes. However, most of the information about the formation of secondary minerals through the alteration of primary minerals derives from studies of largely inorganic processes taking place in relatively "clean" environments. The soil, by contrast, is a heterogeneous milieu that is a dynamic part of the biosphere continually changing in response to climatic variations over all scales of time and space. It is not at all surprising that the minerals in the soil can be quite different in their chemical and physical characteristics from those of the "type" minerals formed in more "geological" environments with which they may share a name and ideal crystalline structure (Churchman, 2010). Chadwick and Chorover (2001) made the point that the crisp boundaries in stability diagrams are, in the real world of natural soils, not so clear-cut. However, the effort involved in understanding the real nature of minerals in soils is worthwhile in view of the potential reward of being able to explain and predict properties across different sorts of soils from the nature of their constituents

TABLE 20.1   Definitions of Terms

Term	Definitions[a]	References	Issues with Definitions
Mineral	An element or compound that is normally crystalline and that has formed as a result of geological processes	Gaines et al. (1997)	Crystallinity implies a regularity of structure, but this is dependent on type of analysis. Some materials (e.g., volcanic glass) lack a fixed structure and are referred to as mineraloids; others such as allophane, earlier thought to be amorphous and technically thus not minerals, are now known to be nanocrystalline and hence do qualify as minerals
Primary minerals	Mineral deposited or formed at the same time as the rock containing it	Lapidus (1987)	Minerals in sedimentary and partially metamorphosed rocks may contain secondary minerals from earlier cycles
Secondary minerals	Mineral formed as a result of alteration of preexisting minerals	Adapted from Lapidus (1987)	Minerals commonly altered in several steps; hence all products of 1° mineral alteration are 2° minerals Often referred to as "clay minerals"
Weathering	Weathering is the breakdown of geological deposits by physical, chemical, and biochemical processes • Physical weathering includes breakdown by thermal and mechanical action, generating smaller particles (comminution); chemical weathering includes breakdown by hydrolysis, carbonation, hydration, dissolution, oxidation, and reduction, changing the physical and chemical properties of the original geological deposits	Ashman and Puri (2002) and Buol et al. (2003)	Some regard weathering as encompassing both the breakdown of primary minerals and the synthesis of new secondary minerals, but others distinguish between two phases, *decomposition* and *argillization*, the latter being the synthesis of secondary minerals (mainly clays)
Soil	The natural, 3D body (comprising pedons), typically up to ~1 to 2 m thick (thicknesses can vary markedly), of unconsolidated mineral and organic material mantling the land surface that can support rooted land plants, and which • Is characterized by one or more soil horizons ("layers") that have evolved through additions, losses, transfers, and transformations of energy and matter by interactions of climate, biota, relief, and parent materials through time, and which differ from the material(s) from which they derive • Comprises solids (inorganic and organic matter), liquids, and gases • Is essential to life through recycling of nutrients, carbon, and oxygen • Is nonrenewable in human timescales	Schaetzl and Anderson (2005)	Most definitions of soil fail to encompass and recognize its complexity as the most complex ecosystem on Earth and as a biological habitat and critically important repository for genes. Soil is also being considered increasingly in policy making, for example, as a provider of "ecosystem services" (e.g., Blum et al., 2006) and as "natural capital" (the stock of biotic and abiotic mass that contains energy and organization) (see Sparling et al., 2006, and Robinson et al., 2009)

[a] Working definition for this chapter.

and that of their associations. As discussed in Section 20.4, soil mineralogy has to some extent been in decline as a subdiscipline of soil science and it may be that this is due, at least in part, to the often-unjustified assumption that soil minerals are similar in their properties to those of their well-characterized "types" formed in nonsoil environments. The implications of this erroneous or only partly true assumption, and new directions for soil clay mineralogy, are also discussed in Section 20.4.

This chapter deals with minerals, both primary and secondary, with the processes of weathering and associated clay formation, and with soils. We define each of these terms in Table 20.1, which also includes some alternative definitions, and some issues involved in these definitions.

20.2 Alteration of Primary Minerals

20.2.1 Common Primary Minerals in Soils

The most common primary minerals found in soils are listed in Table 20.2 within their chemical (compositional) types and their mineralogical groupings together with the types of (crystal) structures for these groupings. Table 20.2 also lists chemical formulae for the minerals or groups of minerals and summarizes the general sorts of soils in which they occur and often also their relative abundance in these soils. Other properties of the minerals listed are given in Churchman (2006, Table 3.1). In soils, primary minerals, as residuals of physical and chemical weathering processes, most commonly occur in coarser particles

TABLE 20.2 Structure, Composition, and Soil Occurrences of Common Primary[a] Minerals in Soils

Chemical Type	Group	Structural Type	Common Soil Minerals	Chemical Formula	Related Phases	Soils of Main Occurrence
Silicates[b]	Silica	Tectosilicate	Quartz	SiO_2	Cristobalite Tridymite Opal (biogenic)	Quartz in almost all soils, Nil/minor from basalt
	Feldspar	Tectosilicate	Orthoclase	$KAlSi_3O_8$	Microcline Sanidine (all K-feldspars)	Feldspars occur in many soils, absent from highly weathered soils
			Albite	$NaAlSi_3O_8$	Oligoclase	
			Oligoclase	$Na_xCa_yAlSi_zO_8$ $(x \gg y)$, $(z = 2\text{–}3)$	Andesine	
			Anorthite	$CaAl_2Si_2O_8$		
			Labradorite	$Ca_yNa_xAlSi_zO_8$ $(y \gg x)$, $(z = 2\text{–}3)$	Bytownite (all plagioclases)	
	Zeolite	Tectosilicate	Clinoptilolite	$Na_3K_3(Al_6Si_{30}O_{72}) \cdot 24H_2O$	Erionite Faujasite Hollandite	Rare in soils; analcime formed in high pH saline soils
			Analcime	$Na_{16}Al_{16}Si_{32}O_{96} \cdot 16H_2O$	Laumontite Mordenite	
	Mica	Phyllosilicate (dioctahedral)	Muscovite	$KAl_2AlSi_3O_{10}(OH)_2$	Paragonite Maragarite Glauconite	Widespread
		Phyllosilicate (trioctahedral)	Biotite	$K(MgFe^{II})_3AlSi_3O_{10}(OH)_2$	Phlogopite Clintonite Lepidolite	Only in slightly weathered soils
	Chlorite	Phyllosilicate	Chlorite	$(Fe,Mg,Al)_6(Si,Al)_4O_{10}(OH)_8$	Cookeite Sudoite Bonbassite	Only in very slightly weathered ("raw") soils
	Serpentine	Phyllosilicate	Chrysotile	$Mg_3Si_2O_5(OH)_4$	Antigorite Lizardite Amesite Berthierine	Rare in soils
	Amphibole	Inosilicate (double chain)	Hornblende	$(Ca,Na)_{2.3}(Mg,Fe,Al)_5(Si,Al)_8O_{22}(OH)_2$	Tremolite Actinolite Cummingtonite Glaucophane	Quite widespread, but absent from highly weathered soils
	Pyroxene	Inosilicate (single chain)	Augite	$(Ca,Na)(Mg,Al,Fe)(Si,Al)_2O_6$	Enstatite Hypersthene Diopside Pigeonite Jadeite Spodumene Hedenbergite	Relatively rare except in some volcanic soils (especially intermediate-basic)
	(Cyclosilicate)	Cyclosilicate	Tourmaline	$(Na,Ca)(Li,Mg,Al)(Li,Fe,Mn)_6(BO_3)_3Si_6O_{18}(OH)_4$	Beryl	Rare
	(Sorosilicate)	Sorosilicate	Epidote	$Ca_2(Al,Fe)Al_2O(Si_2O_7)SiO_4(OH)_4$	Zoisite	Uncommon
	Olivine	Nesosilicate	Forsterite	Mg_2SiO_4	Fayalite Tephroite Monticellite	Rare
	Garnet	Nesosilicate	Almandine	$Fe_3Al_2(SiO_4)_3$		Rare
	Zircon	Nesosilicate	Zircon	$ZrSiO_4$	Baddeleyite (ZrO_2)	Widespread

TABLE 20.2 (continued)   Structure, Composition, and Soil Occurrences of Common Primary[a] Minerals in Soils

Chemical Type	Group	Structural Type	Common Soil Minerals	Chemical Formula	Related Phases	Soils of Main Occurrence
Nonsilicates	Phosphates	Insular, hexagonal	Apatite	$Ca_5(PO_4)_3(OH,F,Cl)$	Fluorapatite Hydroxyapatite Variscite Wavellite Monazite	Some in "raw" soils
	Titanium oxide	Tetragonal	Rutile	TiO_2	Brookite Sphene ($CaTiSi_5$)	Widespread in small amounts
	Carbonate	Rhombohedral	Calcite	$CaCO_3$	Aragonite Siderite ($FeCO_3$)	Common in arid soils
	Carbonate	Rhombohedral	Dolomite	$CaMg(CO_3)_2$	Ankerite Mg calcite	From dolomitic rocks
	Iron oxide	Cubic	Magnetite	Fe_3O_4	Titanomagnetite	Rare except in some volcanic soils and in soils derived from detrital volcanic deposits

[a] Some are also formed in soils, hence may also be regarded as secondary minerals.

[b] Volcanic glass (including obsidian) is an amorphous solid with a poorly ordered internal structure comprising loosely linked SiO_4 tetrahedra (Fisher and Schminke, 1984). Of widely varying composition, it is a common primary mineraloid in many volcanic soils and derivatives.

(of sand- and silt-size), although the phyllosilicates such as the micas, chlorite, vermiculite, and talc, and some oxides, such as those of titanium and also apatite, and volcanic glass, can also be found in reasonable proportions in the clay-size factions of some soils.

20.2.2 Observations of Relative Stabilities of Primary Minerals in Soils

In most cases, weathering involves the reaction of minerals (or mineraloids) with water, or, at least, an aqueous solution. There are exceptions where alteration of primary minerals occurs but where liquid water is either absent or is not the primary agent effecting alteration. This is the case in cold (and polar) and also hot desert zones on Earth (Shoji et al., 2006). It is probably also the case in some extraterrestrial environments, such as the Moon, but not in others, such as Mars, where there is abundant evidence for liquid water, at least in the past (Certini and Scalenghe, 2006). In environments where liquid water does not provide the main weathering milieu, the dominant agents of alteration nonetheless involve climatic factors; hence, they constitute weathering. These include mainly physical actions such as frost wedging and successive freezing and thawing in cold desert zones on Earth (Shoji et al., 2006), processes such as wind ablation in both hot and cold terrestrial desert zones, and such processes as solar wind irradiation on Moon (Certini and Scalenghe, 2006), and perhaps also on other dry extraterrestrial bodies and regions. Other agents besides the purely climatic can also alter primary minerals, given enough time. Among these are some resulting from various human activities (Certini and Scalenghe, 2006), including agriculture (Velde and Meunier, 2008), mining (Murakami et al., 1996; Banfield and Murakami, 1998), landfills

(Batchelder et al., 1998), industrial pollution (Rampazzo and Blum, 1992; Yaron et al., 2010), and probably also global climate change (Berg and Banwart, 2000; Amundson, 2001; Leifeld, 2006). Most of these agents affect mineral alteration via aqueous solutions, although in some cases, for example, the oxidation of sulfides, particularly iron pyrite, alteration of minerals occurs when water is absent (Dent and Pons, 1995). Nevertheless, alteration by weathering most often occurs in an aqueous environment and the most important determinant of the relative stability of primary minerals to weathering is their relative solubility in water.

All minerals have some solubility in water. Only rarely, however, for example, for simple salts like halite (NaCl) found, for example, in arid and saline soils, do they dissolve congruently in water. Instead, hydrolysis commonly occurs with the more soluble components being removed selectively from the mineral. This removal may leave a solid residue, which differs in composition from the original mineral, or a solid alteration product that precipitates out of the solution. The solid precipitate will most likely have a different composition and perhaps also a different crystal structure from that of its antecedent (partly or completely) dissolved mineral. Some texts refer to the synthesis or precipitation of such products as "argillization," meaning the formation of clay; in this case, the term "weathering" encompasses only the decompositional phase (Figure 20.1) (e.g., Buol et al., 2003). Another term widely used is neogenesis, effectively the formation or synthesis of new clays and other secondary material from the breakdown products of antecedent minerals.

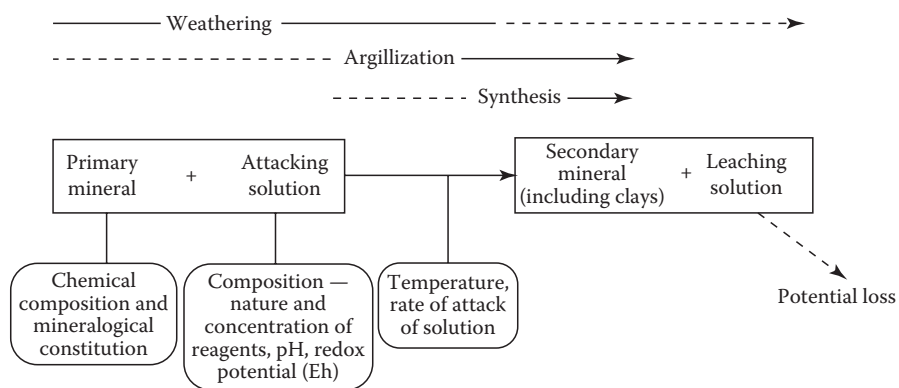
A simple chemical analogy of the hydrolysis undergone by silicates, the most common type of primary mineral, in water, is realized when they are considered as salts of silicic acid H_4SiO_4 and bases of the appropriate cation (Carroll, 1970; Chamley, 1989).


FIGURE 20.1 Weathering (and associated processes of argillization and synthesis) in relation to the factors governing the genesis of secondary minerals including clays in soils. Box 20.1   Hydrolysis of K-Feldspar, Interpreted as a Salt, to Form Kaolinite

Silicate minerals ≡ salt of silicic acid plus base of appropriate cation

$$\therefore \quad \text{K-feldspar} \equiv \text{silicic acid} + \text{hydroxyl-Al } (+K^+)$$

$$\therefore \quad 2KAlSi_3O_8 + 11H_2O \rightarrow Al_2Si_2O_5(OH)_4 + 4H_4SiO_4 + 2K^+ + 2OH^- \tag{20.1}$$
$$\text{K-feldspar} \text{kaolinite} \text{silicic acid}$$

or $\qquad\qquad 2KAlSi_3O_8 + 9H_2O + 2H^+ \rightarrow Al_2Si_2O_5(OH)_4 + 4H_4SiO_4 + 2K^+ \tag{20.1a}$
The hydrolysis of silicates in water results in an acid, namely, silicic acid, and a base, namely, the hydroxy-Al–Si, kaolinite (see Box 20.1). Because most aqueous solutions in which weathering takes place are acidic because water is charged with dissolved CO_2, giving rise to a continuous supply of carbonic acid H_2CO_3 and hence H^+ ions, hydrogen ions are important weathering agents. Therefore, Equation 20.1a represents the natural situation more realistically than Equation 20.1.

The relative stabilities of the principal primary minerals in soils to alteration have long been studied. More than 70 years ago, Goldich (1938) drew up a stability series for these minerals (Figure 20.2) that has generally stood the test of time and further experimentation, for example, by Franke and Teschner-Steinhardt (1994).

20.2.3 Thermodynamic and Structural Explanations of Relative Stabilities

Goldich's series (Figure 20.2) makes thermodynamic sense insofar as the minerals therein are in the identical (but reversed) order to those in Bowen's classic reaction series describing the order in which the minerals crystallized out of a magma on cooling (Bowen, 1922). Goldich (1938) reasoned that the higher the temperature at which a mineral crystallized from magma, the greater the extent to which it was out of equilibrium with the surface temperature of Earth and, therefore, the more susceptible it would be to breakdown by weathering at the Earth's surface.

The alteration of a particular mineral or mineraloid begins with the disruption of its weakest bond. Structural explanations of the relative stabilities of minerals have followed this generalization. Bonds in all silicates are based on silica tetrahedra. Their strength depends on the following: (1) the nature of the links between tetrahedra, (2) the extent of substitution of four-valency Si within tetrahedra by three-valency Al and hence gain of negative charge (isomorphous substitution), and (3) the extent of incorporation of charge-balancing cations, and their location, in the structure. In Table 20.3, we show the nature of bonding in the different structural types of silicates (see Table 20.2 to identify the relevant minerals).

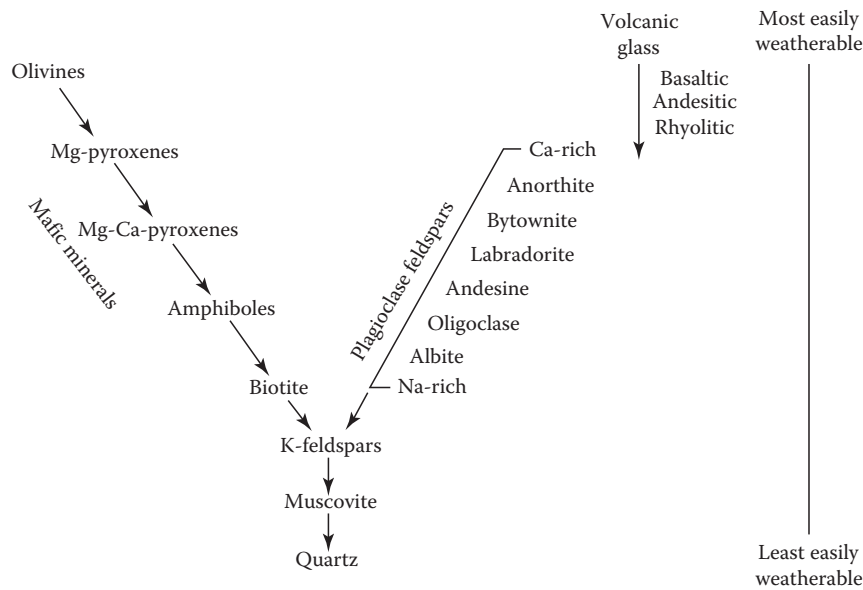
Sposito (1989) pointed to an apparent correspondence between the ordering of the molar Si:O ratios in the silicate units, namely, olivines < pyroxenes < amphiboles < micas < feldspars = quartz


FIGURE 20.2 Stability series for the common primary minerals (after Goldich, S.S. 1938. A study in rock weathering. J. Geol. 46:17–58.) and also volcanic glass (not part of the Goldich series). Basaltic and other glasses, and olivines, are normally the first phases altered by weathering (Wolff-Boenisch, D. et al., 2004).

TABLE 20.3 The Nature of Bonding and the Weakest Bonds in Different Types of Silicates That Are Common in Soils (in Order of Decreasing Stability)[a]

| Structural Type | Group Name | Silicate Unit | | | Examples |
		Formula, Structure	Shared O per Si	Weakest Bonds	
Framework	Tectosilicates	SiO_2	4	Si–O	Quartz
	Tectosilicates	SiO_2, with Al substitution	4	With cations (K^+, Na^+, and Ca^{2+})	Feldspars
Layer	Phyllosilicates	$Si_2O_5^{2-}$, with Al substitution, as a sheet joined to Al-, Mg-, Fe-OH sheet	3	With interlayer cations, usually K^+	Micas
Single chains	Inosilicates	SiO_3^{2-}, with Al substitution	2.5	With divalent, and other cations	Pyroxenes
Double chains	Inosilicates	$Si_4O_{11}^{6-}$, with Al substitution	2	With divalent, and other cations	Amphiboles
Isolated tetrahedra	Nesosilicates	SiO_4^{2-}	0	With divalent cations	Olivines

[a] Cyclosilicates (e.g., tourmaline) have two O bonds per Si and sorosilicates (e.g., epidote) have one O bond per Si, but neither is common in soils (Table 20.2).

and that in the Goldich series. Nonetheless, reference to Table 20.3 may lead to oversimplification concerning possible structural control on the relative stability of silicates to weathering, especially when other silicates besides those in the broad groups represented by both types of ordering are considered. Following Loughnan (1969), for example, we note that both zircon ($ZrSiO_4$) and andalusite (Al_2SiO_5) are neosilicates like olivine and have $(Si:O)_{molar}$ ratios of 0.25 and 0.2, respectively, which are equal or less than those of olivine and yet are both very stable (i.e., resistant) to breakdown by weathering, in contrast to olivine, which is notably unstable according to Goldich's (1938) series (Figure 20.2). Furthermore, the broad classifications shown in Table 20.3 hide the observed differences in the stabilities between individual minerals within structural types. Within the phyllosilicate mica group, biotites are generally much less stable than muscovites, whereas the tectosilicate feldspars include albites and anorthites, each with quite different stabilities.

Another danger of oversimplification arises because weathering (and argillization) is not simply a matter of dissolution of the silicate minerals in water. Instead, weathering often occurs in an acid environment and, commonly in soils, also involves a range of organic compounds, which can complex the ions in the silicate structure and can both enhance their breakdown and affect its course and the products formed (e.g., Velde and Barré, 2010).

The rate at which hydrolysis affects cations released is related to the strength of the bonds formed by the cations within the minerals, according to Pauling's electrostatic valency principle (Pauling, 1929). The ratio of the valency (the charge on the ion) to the coordination number (the number of ions of opposite charge surrounding an ion) is known as the electrostatic valency. The smaller its value, the greater the ease of hydrolysis (Paton et al., 1995). The hydrolysis, or replacement of a cation in a crystal structure by H^+, of K is relatively easy because it is univalent (K^+).

It is commonly found in feldspars, where its coordination number is 9, and in micas, where it has a coordination number of 12. Hence, the electrostatic valency of K in these minerals is 1:9 and 1:12, respectively (Paton et al., 1995). The hydrolysis of Al is more difficult because it is trivalent (Al^{3+}), with coordination numbers of 6 or 4, so the electrostatic valency of Al in primary minerals is either 1:2 or 3:4. These differences between cations, and also between the same cations in different minerals, are reflected in the relative responses of the four main groups of silicates to weathering pressures (Paton et al., 1995). The solubility or relative mobility of various ions such as Ca, K, and Mg relates to ionic potential, which is the ionic charge (valency) divided by the ionic radius (size), so that ions with a low ionic potential such as Na^+, K^+, Ca^{2+}, and Mn^{2+} are more easily leached (lost) in solution, although temperature and pH affect solubility as well (Schaetzl and Anderson, 2005).

Some components of the silicate framework can greatly influence the rate and nature of their breakdown. Chief among these is Fe. According to Millot (1970), the most important weathering reactions involve Fe, a component of many of the primary minerals involved in soil formation (Table 20.2). Along with Mn, which is less abundant in the primary soil-forming minerals (Table 20.2), Fe generally occurs in its reduced form in primary minerals. Fe occurs as Fe(II) and Mn as Mn(II). These are both easily converted to their oxidized forms—Fe(III) and Mn(IV)—when oxidation occurs, for example, when soils dry. This change in valency sets up a charge imbalance in the appropriate minerals, leading to a loss of other ions from the mineral structures, which can destabilize the minerals, enhancing their further breakdown by hydrolysis, which is assisted by the hydrogen ions produced during oxidation. The oxidized forms of Fe and Mn occur as oxides and oxyhydroxides and those of Fe, in particular, are almost ubiquitous in soils. Seasonal wetting and drying cause alternate oxidation and reduction of Mn(II) and Mn(IV) and lead to the common precipitation of the blue-black mineral pyrolusite (MnO_2)—as well as other forms of MnO_2 such as todorokite (Churchman et al., 2010)—as redox segregations (also known as redox concentrations) in the form of coatings (mangans), nodules, or concretions (Vepraskas, 1992; Birkeland, 1999). Manganese oxides in most conditions form preferably to those of Fe during wetting and drying because of the greater ease of acceptance of electrons by Mn than by Fe. The reduction of Fe(III) to Fe(II), commonly by organisms during phases in which a soil is waterlogged, and then its oxidation on drying, leads to Fe oxides being precipitated as mottles, coatings, or concretions. The persistence of reducing conditions causes soil matrix materials to have pale, low-chroma colors (described as redox depletions), and these grayish colors characterize continuously reduced soils that, therefore, have few or no redox segregations (Birkeland, 1999; Vepraskas et al., 2004; Morgan and Stolt, 2006). Brinkman (1970) characterized the clay decomposition brought about by cyclical alternation of redox conditions by the name of "ferrolysis." Even so, a reexamination of some texture-contrast soils having coarser topsoils than subsoils by Van Ranst and De Coninck (2002) found that such coarsening with depth could be more easily attributed to the translocation of clay than to its destruction.

Weathering and argillization, together with soil formation, generally occur in a dynamic system that is open to the wider environment. Leaching—the removal or loss of material in solution—commonly occurs. The driving force that provides the chemical potential energy for mineral alteration is the difference in composition between the "attacking" solution and the solid mineral. However, it is the rate of leaching, which governs the rate of removal of solutes, which most influences the rate of mineral alteration and any subsequent precipitation (Figure 20.1). It also influences the course that the alteration takes. Garrels and Mackenzie (1971) stated that, given sufficient leaching, almost all rocks or unconsolidated deposits will leave a residue that is largely composed of the relatively insoluble oxides of Al, Fe, and Ti.

Hence, the origin of primary minerals as given by their temperature of crystallization from magma influences their thermodynamic stability against breakdown by weathering in an aqueous environment, as does their structure and their particular chemical composition (Figure 20.1). However, such environmental factors as the particular composition of the solutions bathing the minerals, the dynamics of the redox conditions, and the rate of throughflow of water past the minerals can play a decisive role in the kinetics, course, and ultimate products of their alteration.

20.2.4 Processes and Products of Alteration of the Main Types of Primary Minerals by Weathering

Early work exploring either the fate of primary minerals or the origin of secondary minerals on weathering (e.g., Jackson et al., 1948) tended to take the stance that specific primary minerals have led to particular secondary minerals as products. A 1:1 correspondence between altered rock-forming mineral and phyllosilicate product appears justified when one dominant type of primary mineral is altered more than others in the parent material and the overlying soil, saprolite, or regolith more generally is dominated by just one type of secondary mineral (clay). Some modern studies have also concluded that each type of primary mineral generally leads to one particular type of secondary mineral. Thus, according to a generalization by Wilson (2006), the weathering of granite rocks leads most commonly to kaolin minerals (kaolinite and halloysite), largely deriving from the alteration of feldspars, and vermiculite minerals from the alteration of micas. Furthermore, many clay minerals appear to be found in close proximity to particular types of altered primary minerals, for example, halloysite tubes on altered feldspar (Figure 20.3). Clay minerals may also have a morphology that appears to mimic that of altering or altered primary minerals. The similarity in shapes between vermicular books of kaolinite and degraded micas, often occurring as some form of vermiculite (Figure 20.4), can be suggestive of a micaceous origin for the particular kaolinite. To examine whether there is always a 1:1 relationship between particular
FIGURE 20.3 Scanning electron micrograph of tubular halloysite occurring in close proximity to weathered feldspar in granitic saprolite from Hong Kong. (Photo by Stuart McClure. Reproduced with the permission of the Geotechnical Engineering Office, Civil Engineering Office, Hong Kong.)

primary minerals and specific secondary minerals, the following subsections summarize studies that have concentrated on the fate of individual types of primary minerals to alteration by weathering. In these subsections, the generalizations have often been drawn from studies of the weathering of rocks or other geological deposits, the minerals derived from these, and at depth within soil profiles. The influence of particular soil factors on the alterations and products of weathering is discussed in Section 20.2.5.

20.2.4.1 Processes and Products of Alteration of Olivines, Pyroxenes, and Amphiboles by Weathering

In an open environment, generally unstable olivines easily lose Mg^{2+}, and Fe^{2+} (or Mn^{2+} if manganous) to give, first serpentine, then a smectite (commonly saponite), and also goethite, which together have been characterized as "iddingsite" (Loughnan, 1969; Nahon et al., 1982; Eggleton, 1984). Both optical (Craig and Loughnan, 1964) and electron microscopy (Eggleton, 1984) have enabled identification of iddingsite as a mixture of saponite and goethite. Nahon et al. (1982) made the important observation that an aluminous dioctahedral smectite had formed from the breakdown of the Mg-olivine, forsterite (Mg_2SiO_4), which contains very little Al. They suggested that Al probably derived from the simultaneous breakdown of a pyroxene, enstatite. Secondary minerals could, therefore, derive their elemental constituents from the breakdown of more than one primary mineral. Indeed, olivines could give rise to a variety of secondary mineral products, including smectite, kaolinite, halloysite, and also various oxides, hydroxides, and oxyhydroxides of Fe, and, if present, also Mn, upon leaching (Huang, 1989).

Pyroxenes and amphiboles, although slightly more stable than olivines, tend to break down in a similar fashion to the olivines in the field, with an initial loss of their divalent cations, typically Mg, Ca, and Fe(II). Chlorite and/or smectite often result, although talc may also be formed. Calcite can also form as one of the products if Ca is released in abundance (Loughnan, 1969; Eggleton and Boland, 1982; Huang, 1989). Examination at the fine scale of the mineral grain revealed that amphibole weathering led to a dioctahedral (montmorillonite) and a trioctahedral (saponite) smectite, and also kaolinite–smectite simultaneously at the early stages of alteration, with halloysite developing with time (Proust et al., 2006). The different products were associated with different crystallographic faces of the host amphibole (see Section 20.2.5.1). As with olivines, pyroxenes and amphiboles could give rise to products with simpler structures, such as kaolinite, Fe(III) oxides, and anatase upon strong leaching (see also Wilson, 2004). The common pathway of alteration of this group of minerals by weathering is shown in Box 20.2.

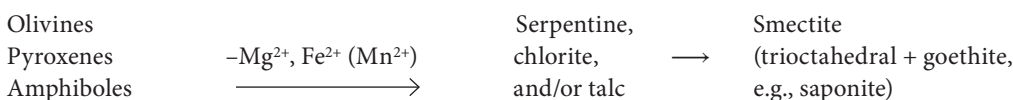
Many laboratory studies have been designed to help understand the initial stages of alteration of these ferromagnesian minerals. At low pH, divalent ions are lost relative to silica, whereas the converse occurs at high pH with a preferential loss of Si (Schott and Berner, 1985). It has usually been inferred that leached layers, depleted in some of their original constituents, develop as a result on mineral surfaces (Schott and Berner, 1985; Banfield et al., 1995). Experimental studies (e.g., Velbel, 1985) have often indicated weathering rates that far exceed those observed in nature by up to 5 orders of magnitude (Banfield and Barker, 1994).

However, by following evidence from electron microscopy particularly, weathering of olivines, pyroxenes, and amphiboles has been seen to involve the formation, enlargement, and coalescence of etch pits developed on crystal dislocations

<div style="border:1px solid black;">

Box 20.2 Initial Alteration of Olivines, Pyroxenes, and Amphiboles as Commonly Reported

Olivines		Serpentine,		Smectite
Pyroxenes	$-Mg^{2+}, Fe^{2+} (Mn^{2+})$	chlorite,	$\longrightarrow$	(trioctahedral + goethite,
Amphiboles	$\longrightarrow$	and/or talc		e.g., saponite)

</div>


(Huang, 1989; Hodder et al., 1991; Seyama et al., 1996; Wilson, 2004) rather than through an enleached layer. Velbel and Barker (2008) have acknowledged that surface tension upon air-drying samples for conventional scanning electron microscopy (SEM) may affect surface structure and have examined partially weathered pyroxenes using high-pressure cryofixation (HPF) and cryo-field emission gun SEM, both of which avoid the surface tension effects of air-drying. They were thus able to view the products formed in small-scale etch pits on the pyroxenes and have concluded that pyroxene weathers to smectite by a multistage process. Velbel and Barker (2008) proposed that the process includes initial dissolution, topotactic reactions, mechanical disruption from wetting and drying cycles, further dissolution and, eventually, microbial colonization of the pores, with weathering finally enhanced by microbial extracellular polymers. As for the alteration of feldspars (see Section 20.2.4.2), the findings from laboratory studies may not reflect the processes occurring in the field because of oversimplification of the factors involved in natural weathering.

Nonetheless, Mogk and Locke (1988), using Auger electron spectroscopy (AES), found that naturally weathered hornblende showed systematic cation depletion to depths of ~120 nm. They considered that the dissolution of minerals generally occurs from both their surfaces and their bulk. Furthermore, Welch and Banfield (2002) were able to produce microstructural channeling effects in the olivine, fayalite, from laboratory dissolution experiments with an initial pH of 2.0, which were identical to those seen in the naturally weathered mineral (e.g., Banfield et al., 1991). X-ray photoelectron spectroscopy (XPS) had shown earlier that surfaces are coated by films of Fe(III) oxides both at low and high pH (Schott and Berner, 1985; Casey et al., 1993; Seyama et al., 1996), and Welch and Banfield (2002) found that when either microbes that enzymatically oxidize iron or instead ferric iron was added to the system, the minerals degraded at a greatly reduced rate. They identified the formation of laihunite, a ferric–ferrous olivine-like mineral containing vacant atomic sites, in the region of the mineral surface. This laihunite would protect the mineral against further dissolution.

Generally, alteration of primary minerals to give secondary products involves either transformation within the solid state or neoformation, with either partial or complete dissolution of solutes, then their reprecipitation as new secondary phases. Structural considerations appear to dictate that neither the neosilicate olivines, with independent silica tetrahedra, nor the inosilicate pyroxenes and amphiboles with tetrahedra in chains, can transform directly within the solid state to phyllosilicate clay minerals with flat sheets. Nevertheless, high-resolution transmission electron microscopy (HRTEM) observations of weathering amphiboles led Banfield and Barker (1994) to conclude that a type of transformation of amphiboles to smectites can occur within the solid state. They observed these reactions occurring in interstitial spaces within the primary amphiboles, with secondary smectites formed in a topotactic relationship to the altering amphibole. The change was described as a partial depolymerization of the amphibole structure leading to a repolymerization to that of smectite. There is no need for bulk water to bring about this change, with the water of hydration of the smectite product being able to supply the water required for the transformation reaction. Although Banfield and Barker (1994) pointed out that this type of transformation is not representative of all weathering reactions, it enables episodic alteration to take place within rocks or geological deposits, where it is limited by an intermittent supply of water and, therefore, much slower than that occurring on the surfaces of rocks or rock minerals immersed in aqueous solution. Banfield et al. (1995) found that smectites could form within weathering pyroxenoids (rhodonite and pyroxmangite, both $MnSiO_3$), which were studied by a similar type of in situ transformation. Periodic drying, which often occurs in this situation, may promote the repolymerization of phyllosilicates rather than depolymerized silica (Banfield et al., 1995). The reaction has little significance for soil formation, however, because the smectitic products are "quite ephemeral" and disappear when transported from the altered rock into the more open soil environment (Wilson, 2004).

Not all workers have considered that the primary ferromagnesian minerals are altered directly to phyllosilicates such as smectites. Nahon and Colin (1982) and Singh and Gilkes (1993) both identified amorphous or noncrystalline intermediates in the alteration of (different) pyroxenes. In comparing this observation with those of Banfield and coworkers, among others, who

observed direct formation of phyllosilicates on altering ferro-magnesian minerals, Wilson (2004) cautioned that the course of formation of phyllosilicates may have been established by prior hydrothermal or deuteric alteration in the latter cases and alteration by weathering had continued along the predisposed course.

20.2.4.2 Processes and Products of Alteration of Feldspars by Weathering

Feldspars have been thought to give rise to many different types of secondary minerals, encompassing the range of structural complexity from smectites through to gibbsite and quartz. Allen and Hajek's (1989) review referred to several studies where smectites have been identified as products of the alteration of feldspars. These authors surmised that the resultant smectites would be beidellitic because the parent feldspars lacked Mg or Fe, and Nettleton et al. (1970) characterized a smectite seen to form directly from a feldspar crystal as a beidellite–montmorillonite. Reports of the alteration of feldspars to gibbsite and quartz, at the lower end of the scale of structural complexity, were given by Allen and Hajek (1989) and Estoule-Choux et al. (1995). Otherwise, feldspars have been considered as the source minerals for micas (Carroll, 1970; Millot, 1970) and very often also for kaolinites and halloysites (Eswaran and Wong, 1978; Calvert et al., 1980; Anand et al., 1985). The micaceous minerals formed from feldspars, both K-feldspars and plagioclases, have often been described as "sericites," with the process of their formation being described as sericitization (Carroll, 1970; Millot, 1970). However, the term sericite has also been used to describe white mica formed from the reaction of biotite with plagioclase during metamorphism (Meunier and Velde, 1976). Furthermore, orthoclase (a K-feldspar) has been considered to hydrolyze to muscovite (Hemley, 1959). On the contrary, Meunier and Velde (1979) found that the micaceous phase, which they considered to be an illite, developed at a boundary between muscovite and orthoclase within weathering granite, and contained more Fe and Mg than either the muscovite or orthoclase. Hence, the illite formed (precipitated) out of solution. Using electron microscopy, Eggleton and Buseck (1980) detected micaceous phases forming within vacuoles within microcline. They considered these to be either illite or interstratified illite–smectite. Bétard et al. (2009) found that an illite formed within nonalkali feldspar (a plagioclase) by neoformation in Luvisols in northeast Brazil, and, more generally, they considered this particular weathering reaction to be typical of semiarid tropical and subtropical climates.

Studies of the artificial weathering of feldspars in controlled conditions in the laboratory have largely focused on the possibility of the formation of a leached layer on feldspar surfaces during their alteration. On the one hand, different types of surface-sensitive analyses—including secondary ion mass spectrometry, SIMS (also known as ion microprobe) (Muir and Nesbitt, 1997); elastic recoil detection, ERD, and Rutherford backscattering, RBS (Casey et al., 1988, 1989); and XPS (Muir et al., 1989, 1990; Hellmann et al., 1990)—indicated the formation of a dealkalized leached layer of up to 1 μm deep, especially at low pH. The leached product from an albite was identified as an amorphous phase with some of the characteristics of nanocrystalline allophane, which later became detached (Kawano and Tomita, 1994). The fate of the leached layer was found to be dependent upon the Si:Al ratio in the parent feldspar (Oelkers and Schott, 1995). Where this ratio was 1, as in plagioclases (anorthite was studied), the removal of Al led to completely detached silica tetrahedra, but where it was 3, as in alkali feldspars, Si tetrahedra that were still partially linked remained.

On the other hand, some measurements by XPS (Berner and Holdren, 1979) showed no leached layer forming, and when the artificial alteration was carried out at near-neutral pH values (between 5 and 8), rather than at low pH, the layer formed was only thin (Blum and Stillings, 1995). Huang (1989) concluded that, in any case, leached layers are not thick enough to inhibit transport and also that there were no continuous layers of secondary precipitates on weathered feldspars. As in the case of olivines, pyroxenes, and amphiboles, dissolution of feldspars probably occurred at sites of excess energy such as dislocations (Huang, 1989).

HRTEM studies have shown that unweathered feldspars are often turbid as a result of minute vesicles being filled with fluid (Hochella and Banfield, 1995), consistent with the observation that they can have a high microporosity (Worden et al., 1990). HRTEM has also shown that their alteration often occurs preferentially at crystal defects (Wilson and McHardy, 1980; Holdren and Speyer, 1987) and that secondary minerals form throughout the primary mineral, not just at grain boundaries (Banfield and Eggleton, 1989; Banfield et al., 1991). Application of SEM and associated energy-dispersive x-ray (EDX) analyses showed etch pits and secondary coatings (of a kaolin mineral) developing as the weathering alteration of feldspars progressed (Inskeep et al., 1993). These authors saw the formation of secondary coatings on feldspars as an integral part of their alteration. These were not observed in artificial weathering studies. Essential features of weathering in the field include those of seasonal wetting and drying, a generally high solid:solution ratio, and long residence times for water (Inskeep et al., 1993). The net effect is a weathering rate, determined for plagioclases, that is several orders of magnitude slower than the experimental dissolution rate (White et al., 1996, 2005; White and Brantley, 2003). Maher et al. (2009) have shown that other factors besides mineral dissolution rate and the rate of aqueous transport of solutes, notably the rate of secondary mineral precipitation, ensure a much slower rate of weathering of minerals, including feldspars, in the field than in the laboratory. Furthermore, fungi have been shown to contribute to the breakdown of feldspars on weathering, partly, at least, through their tunneling by organic anions exuded at the tips of the hyphae of (presumably ectomycorrhizal) fungae (Smits et al., 2005; see also Section 20.2.5.3 on podzolization). Failure to reproduce these features in necessarily hastened artificial weathering studies under closely controlled conditions almost certainly means that their results cannot be applied readily to the understanding of natural weathering.

20.2.4.3 Processes and Products of Alteration of Micas by Weathering

Changes from any of the neosilicate olivines, with independent silica tetrahedra, the inosilicate pyroxenes and amphiboles with tetrahedra in chains, and the tectosilicate feldspars with continuous frameworks of silica and alumina tetrahedral, to yield phyllosilicate clay minerals with flat layers, all involve some dissolution and recrystallization. These processes usually occur within the solution phase, when they can confidently be labeled as neogenesis, although, as we have seen from Banfield and coworkers, descriptions (see Section 20.2.4.1), neogenesis can also take place by a type of transformation within the solid phase that involves successive depolymerization and repolymerization. By contrast, phyllosilicate micas can transform easily to phyllosilicate clay minerals in the solid state.

The main changes that occur in these transformations are exchange of the interlayer cations and reduction in the charge of the layers. Potassium ions occupy the interlayer regions of the common micas, biotite and muscovite. The replacement of K^+ by hydrated cations such as Mg or Ca leads to a loss of strength of binding between adjacent layers. The interlayers expand, so that, with complete replacement by hydrated divalent cations, the basal spacing increases from 1.0 to 1.4 nm and vermiculite is formed. The concomitant reduction in layer charge has been supposed to occur by a wide variety of mechanisms. These include incorporation of protons into the layers (Raman and Jackson, 1966; Leonard and Weed, 1967), exchange of Si for Al in the tetrahedral sheet (Jackson, 1964; Sridhar and Jackson, 1974; Vicente et al., 1977), loss of hydroxyls (Stucki and Roth, 1977), and the deprotonation of hydroxyl groups and the loss of octahedral Fe, both occurring together (Farmer et al., 1971; Douglas, 1989; Fanning et al., 1989).

In soils particularly, micas rarely transform completely to vermiculite. In soil science, the term "illite" is most commonly used to describe clay-sized micaceous minerals. According to Grim et al.'s (1937) original definition of illite, it was "a general term for the mica-like clay minerals occurring in argillaceous sediments," which also "showed substantially no expanding lattice characteristics." It tends to be used more widely in practice. Illites commonly show a deficit of K and an excess of water in comparison with muscovite or biotite. This deficit reflects the greater ease of loss of K from micas that are fine grained rather than coarse, together with a paradoxical especially strong retention of some K in the fine-grained micas against replacement, both in nature and in the laboratory (Fanning et al., 1989).

Fine-grained micaceous minerals that include some expanding layers are sometimes also called illite (Grim, 1968; Wentworth, 1970; Norrish and Pickering, 1983; Weaver, 1989; Laird and Nater, 1993). Strictly speaking, however, these are interstratified illite (or mica)–vermiculites (or smectites). The interstratification may be either random or regular. If they are regular, with close to a 1:1 mix of the two constituent layer types, these two types alternate and the basal spacing is a sum of the spacings of the unaltered mica layers (1.0 nm) and the hydrous vermiculite layers (1.4 nm), giving a resultant spacing of 2.4 nm.

Alternating layer types in regular 1:1 interstratifications are explained by the replacement of the K ions in one interlayer by hydrated divalent ions, leading to the expansion of this interlayer, causing, in turn, a strengthening of the bond between K^+ and the aluminosilicate layers in the two adjacent interlayers (Bassett, 1959). These bonds probably strengthen because of a shift of structural hydroxyl groups toward the opened interlayer (Norrish, 1973). Regular interstratifications of micas with vermiculite (and also with smectites, as products of further transformation of micas) tend to occur in soils in colder climates, such as the upland regions of the former Yugoslavia (Gjems, 1970), Scotland (Wilson, 1970), Scandinavia (Kapoor, 1973), and the South Island of New Zealand (Churchman, 1980). In these cold climates, the displacement of interlayer K^+ occurs more slowly and in more discrete steps, that is, via alternate interlayer regions, than in warmer climates, where the transformation occurs more rapidly and in a relatively haphazard fashion to give irregular layer stacking. The release of K^+ from micas is considered to occur by either layer weathering, as proposed by Jackson et al. (1952), or edge weathering, as proposed by Mortland (1958), or both. In the former, most, if not all, of the K^+ in a particular interlayer is released virtually simultaneously. This release commonly occurs in the alteration of clay-sized micas. In edge weathering, K ions are released by diffusion from edges and fractures. This loss by diffusion commonly occurs in the alteration of larger mica flakes and has been observed as fraying in artificially altered micas, but it can also take place alongside layer weathering in clay-size micas (Fanning et al., 1989).

Trioctahedral micas, among them biotite and phlogopite, weather more readily than dioctahedral micas, including muscovite and most illites. Plants can bring about the transformation of biotite to vermiculite through their extraction of K from the mineral (Section 20.2.5.3). Among vermiculites in soils, the dioctahedral forms are more common than their trioctahedral counterparts (Jackson, 1959). Not only are the dioctahedral vermiculites more stable, but also they can form from biotites at the expense of the trioctahedral varieties as a result of a structural rearrangement whereby some octahedral cations are lost from the structure only to be replaced by some Al cations that are lost from tetrahedral sites (Douglas, 1989).

Transformation of micas in soils to expandable phases often occurs under acidic conditions. When pHs are relatively low (ca. 5 ± 0.5) and organic matter contents are low, Al is mobile in the aqueous phase as hydroxyl cations, and, where wetting and drying frequently occur, the conditions favor the deposition of Al-hydroxy species in the interlayers of vermiculites (and also smectites; Rich, 1968). The products, which are nonexpandable or only poorly expandable, are known by a variety of names including dioctahedral chlorite, pedogenic chlorite, 2:1–2:2 intergrade, chloritized vermiculite, and hydroxyl-interlayered vermiculite (HIV), and also their smectitic counterparts, such as hydroxyl-interlayered smectite (HIS) (Barnhisel and Bertsch, 1989).

Aluminous interlayers can protect vermiculites from further breakdown (Douglas, 1989) but can be destroyed by chemicals that dissolve Al hydroxyl species, including citrates. Citrates were once used routinely prior to x-ray diffraction (XRD) analyses (Mehra and Jackson, 1960) but their use can lead to the loss of potentially useful genetic information from the occurrence of the aluminous interlayers (Churchman and Bruce, 1988).

Vermiculitization of micas/illites has been found to occur by the expansion of the interlayer region into a wedge shape, known as the "frayed edge site" (Sawhney, 1972; Nakao et al., 2009). Through the use of a measurement known as "radiocesium interception potential" (RIP), which gives the amount of these frayed edge sites, Nakao et al. (2009) have compared minerals in soils that have formed from parent materials containing micas in various parts of Asia for their vermiculitic character in relation to the moisture regimes in which they have formed. RIP measures the selectivity of the frayed edge sites for Cs^+ in comparison with hydrated ions. A high RIP value, indicating a high selectivity for Cs, indicates a high concentration of vermiculite per se, whereas a low value can indicate either that little transformation of illite/mica has occurred or else that hydroxyl-Al interlayering has blocked the frayed edge sites that develop with vermiculitization. Nakao et al. (2009) discovered that, in subtropical Thailand, with an ustic moisture regime in which there is a distinct dry season, illites showed little alteration and, consequently, RIP was low. However, in a strongly leaching udic moisture regime and hyperthermic temperature regime in Indonesia, an advanced degree of vermiculitization was indicated by a high RIP. By contrast, an udic and mesic moisture regime in temperate Japan, while also producing a high degree of vermiculitization, nonetheless gave a low RIP value. This result arose because hydroxyl-Al interlayers blocked frayed edges. Nakao et al. (2009) noted that an index of weathering that is based on the degree of vermiculitization showed no relationship with one based on the oxidation status of Fe, which implied that the Thai soil was highly weathered despite its mica/illite showing little or no alteration. The factors that affect the development of Fe oxides in soils and those that affect loss of K^+ from the interlayers of micas and illites need bear no relation to one another. In particular, Nakao et al.'s (2009) results showed that the balance between the time spent by a soil in a dry season and the extent of leaching that occurs plays an important role in determining the extent of vermiculitization of its constituent micaceous phases.

Under low pH conditions, commonly where organic matter contents are high, as they often are under forests, micas may transform to smectites in soils as a result of acid leaching. These conditions typify podzolization and smectites often form through the transformation of micas in the eluviated horizons of podzols. The resulting smectites are generally Al-rich and hence beidellitic (Ross and Mortland, 1966; Churchman, 1980; Borchardt, 1989), but may also be montmorillonitic (Aragoneses and García-González, 1991). Strong weathering without podzolization can also transform micas to smectites (Stoch and Sikora, 1976; Egashira and Tsuda, 1983; Senkayi et al., 1983; Singh and Gilkes, 1991; van Wesemael et al., 1995), even in Antarctic soils, where smectites were among the transformation products of micas (Boyer, 1975). Smectites formed this way have generally been identified as beidellites. Their genesis contrasts strongly with those of most smectites, which form at high pH under poor drainage (see also Section 20.3.5).

Under cool climates, and, with sufficient rainfall, vermiculitic layers that are interstratified with mica layers can themselves be further transformed while the adjacent mica layers remain essentially unaltered. Thus, stepwise transformations of (muscovite) mica, first to regularly interstratified mica–vermiculite, then to regularly interstratified mica–beidellite, have occurred over a climosequence on increasing rainfall on mica–chlorite schist in South Island, New Zealand (Churchman, 1978, 1980). These changes to alternate layers have occurred under a current grassland vegetation, rather than under native forest. Indeed, soils within the area that have formed under forest, but with the same precipitation regime as one of the wetter sites in the climosequence under grassland, showed advanced transformation of the mica to a discrete beidellite phase. It appears that the often more acidic exudates from trees (e.g., Courchesne, 2006) impose a stronger weathering regime than that under grassland, so that the driving force exceeds that leading to transformation of alternate layers alone.

An advantage of many cool-climate studies is that not all primary minerals alter at the same rate, and the origin of secondary minerals can, therefore, be traced to the few, if not single, primary minerals that have altered. In the bulk of Churchman's (1978, 1980) studies, feldspars were fresh and only mica and chlorite showed signs of alteration. In warmer climates and, with sufficient throughflow of water and passage of time, micas break down further to form 1:1 minerals, both kaolinite and halloysite. Although the direct formation of kaolin minerals from micas alone cannot be concluded when other primary minerals have also altered, many workers have established that micas have altered to form kaolins mainly because of the appearance of the secondary minerals as pseudomorphs after the micas. This apparent pseudomorphic replacement applies for kaolinites formed in tropical Nigeria (Ojanuga, 1973), from tertiary weathering in Europe (Stoch and Sikora, 1976), in ferralitic (lateritic) soils in Western Australia (Gilkes and Suddhiprakarn, 1979), and in deeply weathered soils in the continental United States (Rebertus et al., 1986), and also for both halloysite and kaolinite formed alongside each other in close association with biotite in tropical Malaysia (Eswaran and Yeow, 1976).

Mainly with the help of electron microscopy, some workers have even found that kaolin minerals can form from micas early in the weathering process including from both biotite (Ahn and Peacor, 1987; Banfield and Eggleton, 1988) and muscovite (Robertson and Eggleton, 1991). Ahn and Peacor (1987) showed that kaolinite can also form as (irregularly) intercalated layers between biotite layers, presumably by a dissolution/crystallization process whereby one biotite layer gives rise to two kaolinite layers. This change takes place within "plasmic microsystems" (Velde and Meunier, 2008) involving small differences in chemical potentials, which arise because of connections with a major

passageway for water outside a rock or geological deposit. Such an occurrence—the kaolinization of biotite—may have occurred in weathered tephra beds aged ca. 350,000 years in northern New Zealand and which contain biotite in the unweathered parent tephra (Rangitawa tephra). The kaolinized mineral occurs as a sand-sized golden platy mineral. It comprises (using SEM) nearly nine primary (6–8 μm thick), four secondary (1–1.5 μm), and five to seven tertiary (0.7 μm) lamellae units, and was characterized via XRD as a K-depleted, partially random interstratified micaceous kaolinite intergrade containing <50% of 1 M trioctahedral mica and >50% of partially disordered dioctahedral kaolinite (Shepherd, 1984; Lowe and Percival, 1993).

Conversely, some (Eswaran and Yeow, 1976; Gilkes and Suddhiprakarn, 1979) have found that vermiculite—often considered to be an unstable intermediate phase (Kittrick, 1973)—nonetheless occurred alongside kaolin minerals in soils formed under strong leaching. One of the likely reasons for the appearance of apparently early weathering products such as vermiculite alongside apparently late stage products such as kaolin minerals is that iron (oxyhydr)oxides are very common products of the weathering of micas. The secondary iron phases coat other minerals such as vermiculites and preserve them against further breakdown. They include goethite (Sousa and Eswaran, 1975; Eswaran and Yeow, 1976; Gilkes and Suddhiprakarn, 1979; Banfield and Eggleton, 1988) as well as hematite (Gilkes and Suddhiprakarn, 1979). Several studies of the products of natural weathering of micas (Rice and Williams, 1969; Aldridge and Churchman, 1991; Aoudjit et al., 1996; Seyama et al., 1996), using variously Mössbauer and XPS spectroscopy, as well as the laboratory study of Farmer et al. (1971), have shown that total Fe and Fe(II) were depleted from micas on weathering while Fe(III), Fe gels, and Fe(oxyhydr)oxides built up outside the micas. Oxides and hydroxides of other metals, including Al, as gibbsite (Gilkes and Suddhiprakarn, 1979), and also titanium dioxide (Milnes and Fitzpatrick, 1989), may also have formed, at least partially, from micas.

20.2.4.4 Processes and Products of Alteration of Chlorites by Weathering

Chlorites occur most commonly as trioctahedral minerals in parent materials for soils. They originate mainly from low-grade metamorphic rocks and as products of the early alteration of Fe- and Mg-containing primary minerals such as augite, hornblende, biotite, and serpentines (see Section 20.2.4.5). They are not common in soils mainly because of their low stability with regard to weathering. The initial stages of their alteration are similar to those of micas and involve the loss of their interlayer species, most often hydroxides of Mg (i.e., brucite structures), but also those of Fe and other cations. Products of the earliest stages of weathering of chlorites have been identified variously as a randomly interstratified hydrous phase (Churchman, 1980), swelling chlorite, which is a type of chlorite depleted of some of its interlayer hydroxides (Stephen and MacEwan, 1951; Bain and Russell, 1981), and sometimes also regular interstratifications of chlorite and swelling chlorite (Churchman, 1980), as well as a

chlorite/vermiculite intergrade (Murakami et al., 1996). There is also a strong tendency to form 1:1 regular, or "semiregular," chlorite–vermiculite interstratifications at the next early stage of weathering. This mineral type has been observed in weathering by Johnson (1964), Herbillon and Makumbi (1975), Churchman (1980), Banfield and Murakami (1998), and Aspandiar and Eggleton (2002a, 2002b) among others. A study with atomic-resolution transmission electron microscopy (TEM) led Banfield and Murakami (1998) to propose that there was a tendency toward regular 1:1 interstratification because interlayer Mg and Fe (oxyhydr)oxides are removed from every second interlayer on account of a layer shift (of ~a/3) occurring after the removal of one interlayer (oxyhydr)oxide that thereby stabilizes the adjacent interlayer (oxyhydr)oxide. The stabilization means that the (oxyhydr)oxide in the next interlayer is more labile to replacement. However, Wilson (2004) warned that observations of regular chlorite–vermiculite interstratifications should be treated with caution as products of weathering alone because some, at least, of the parent rocks may have undergone prior hydrothermal alteration. Interstratified chlorites and also vermiculite-like phases have been found to occur in some metamorphosed rocks. Nonetheless, not all sequences of alteration of chlorites are the same, with several authors (e.g., McKeague and Brydon, 1970; Bain, 1977; Churchman, 1980; Ross et al., 1982; Righi et al., 1993; Carnicelli et al., 1997) finding that the chlorite component, often of chlorite–mica schists, disappeared as a result of acid weathering in a podzolized soil, or spodosol. Chlorite dissolved, typically leaving a solid residue of iron oxides and oxyhydroxides, for example, goethite (Bain, 1977; Ross et al., 1982). Frequently, however, there is further development of the interstratifications of chlorite with vermiculite to discrete vermiculite (Loveland and Bullock, 1975; Murakami et al., 1996). Often also, smectites are considered to form from chlorite (Herbillon and Makumbi, 1975; Carnicelli et al., 1997). Although the primary chlorites are trioctahedral, the resulting vermiculites and smectites are mostly dioctahedral (Wilson, 2004). Ultimately, kaolin minerals, both kaolinite (Herbillon and Makumbi, 1975; Murakami et al., 1996) and also halloysite (Cho and Mermut, 1992), can result from the strong weathering of chlorites.

20.2.4.5 Processes and Products of Alteration of Serpentines by Weathering

Serpentinite rocks, which are dominated by serpentines (mainly chrysotile, antigorite, and minor lizardite), together with iron oxides and such minerals as amphiboles, pyroxenes, and talc (e.g., Bonifacio et al., 1997), are generally unstable in soils. In central California, this rock type gave rise to virtually pure Fe-rich smectite in the fine clay (<0.2 μm) fraction (Wildman et al., 1968). These authors attributed the mineralogical change to the loss of the more mobile elements Mg and Si and relative enrichment of Fe and Al. In the Massif Central in France, alteration of serpentinite in a poorly drained B horizon led to a trioctahedral chlorite, which is normally regarded as a primary mineral, and also to its alteration products: a regularly interstratified chlorite–vermiculite and a nontronitic smectite

(Ducloux et al., 1976). This change, while involving some loss of Mg and Si—as expected in an open soil system—is more typical of a closed system (Ducloux et al., 1976). The weathering products of a serpentinite in northwest Italy were found to depend strongly on drainage conditions (Bonifacio et al., 1997). Low-charge vermiculite sometimes formed but either dissolved or was transformed to smectite if drainage was poor. An aluminous chlorite could result from either the preformed vermiculite or smectite as a result of interlayering by hydroxy-Al. Lee et al. (2003) in California and Caillaud et al. (2004) in France also found that vermiculite and smectite were formed in the course of weathering of serpentinites. In general, the smectites formed from serpentinites per se are complex and heterogeneous according to Caillaud et al. (2004). Caillaud et al. (2004) focused on a microsystem in the serpentinite weathering system. The types of vermiculite and/or smectite formed varied, with both trioctahedral and dioctahedral structural types covering a range of layer charges, depending upon their originating primary minerals. For instance, a thin lizardite bastite gave rise to Al-poor trioctahedral saponite, whereas a dioctahedral Fe-rich montmorillonite appeared to derive directly from chrysotile. Using a toposequence in Taiwan on serpentinite containing chrysotile, antigorite, and lizardite, and also chlorite and talc, Hseu et al. (2007) were able to identify the products of weathering as, first, smectite that was dominantly trioctahedral, then interstratified chlorite–vermiculite, and, finally, kaolinite and quartz.

20.2.4.6 Processes and Products of Alteration of Volcanic Parent Materials by Weathering

One outstanding feature of volcanic materials as parent materials for clay-size minerals is that they usually contain glass, which is a fast-weathering source of Si and Al (and other elements) for mineral neogenesis. They can also contain other weatherable minerals, depending on their origin, nature, and composition. Broadly, volcanic materials may originate from effusive eruptions, forming lavas, or explosive eruptions that generate fragmental, unconsolidated deposits called pyroclastic materials, or tephra, which may be distributed widely by the wind. Among the latter, there are three main types, based on composition. These are (1) basaltic, which are rich in Fe and Mg, reflecting usually high contents of ferromagnesian, or mafic, minerals, namely, olivines, amphiboles, and pyroxenes, as well as feldspars and brownish-colored basaltic glass low in Si and relatively high in Al; (2) rhyolitic, which have abundant Si-rich glass comparatively low in Al, and which may contain minor amounts of mafic minerals including biotite, and also feldspars; and (3) andesitic or dacitic, which are intermediate in composition between basaltic and rhyolitic eruptives (see Section 33.3, for more details on their composition, occurrences, and properties).

20.2.4.6.1 Glass

The alteration of glass is a special case. Glass is an amorphous solid with a poorly ordered internal structure comprising loosely linked SiO_4 tetrahedra with considerable intermolecular space

(in which cations such as sodium occur) (Fisher and Schminke, 1984). The hydration and breakdown of glass results in fluxes of some elements from the glass into interstitial pore waters, and the very rapid precipitation of secondary minerals from such solutions as well as replacement of glass shards by new minerals (e.g., Daux et al., 1994). Dissolution of basaltic glass, and probably also other glass types, as determined by Oelkers and Gislason (2001) and Gislason and Oelkers (2003), proceeds in effectively three steps: (1) relatively rapid and largely complete removal of univalent and divalent cations from the near-surface glass structure via the breaking of metal–oxygen bonds and their replacement with proton–oxygen bonds, (2) Al-releasing exchange reactions between three aqueous H^+ ions and Al in the glass structure, and (3) relatively slow detachment of partially liberated silica. The tetrahedrally coordinated Si–O bonds are the most stable bonds in the glass framework. Si tetrahedra on the glass surface may be connected to the glass framework via one to three bridging oxygens, and the rate of release of any Si atom at the surface decreases markedly as the number of bridging oxygen bonds increases (Gislason and Oelkers, 2003). The breaking of Al–O bonds does not destroy the glass framework but instead only partially liberates the silica tetrahedral chains by removing adjoining Al atoms (Gislason and Oelkers, 2003). Glass dissolution rates demonstrably increase with decreasing Si content (Wolff-Boenisch et al., 2004), and, hence, basaltic glass (low in Si) usually dissolves faster than andesitic glass (intermediate Si content) or rhyolitic glass (high in Si) under similar environmental conditions (Neall, 1977; Hodder et al., 1990; Shoji et al., 1993b; De Vleeschouwer et al., 2008; Sigfusson et al., 2008; Figure 20.2). In all cases, fragmental and vesicular glass components, such as those which occur in tephra deposits, have high surface areas and are very porous and so break down very quickly, and at rates closely proportional to geometric surface areas (e.g., Dahlgren et al., 2004; Wolff-Boenisch et al., 2004). The initial alteration of basaltic glass, described widely as "palagonitization," is described as a special case in Section 20.2.4.6.3.

20.2.4.6.2 Formation of Allophane and Halloysite from Volcanic Parent Materials

Allophane and halloysite are the most common secondary minerals that are formed in soils developed from loose volcanic material or tephra, which may be ash, pumice, and cinders (the last also referred to as scoria).

Using ^{27}Al and ^{29}Si NMR, Hiradate and Wada (2005) have deduced a mechanism for the formation of allophane from glass as another step in the weathering-synthesis process (Figure 20.5). This mechanism involves (1) dissolution of Al mainly from volcanic glass (via Al-releasing exchange reactions with protons) and its concomitant transformation from its tetrahedral to octahedral state, from ^{IV}Al to ^{VI}Al; (2) hydrolysis of the Al released into solution to give a gibbsite-like sheet; (3) dissolution (via breaking of Si–O bonds) of Si from volcanic glass, where it occurs as a silica gel-like polymer, to give monosilicic acid in solution; and (4) reaction between the gibbsite-like sheet and monosilicic acid to generate allophane.

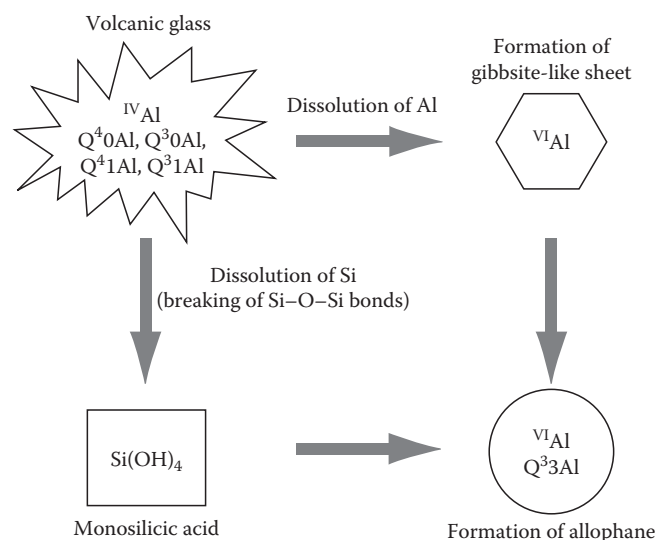
Formation of allophane


FIGURE 20.5 Model depicting the formation of allophane. Q notation describes the connectivity of a Q unit—that is, an Si atom surrounded by four oxygen atoms—to other Si atoms (Wright and Sommerdijk, 2001): Q4 indicates that the Q unit is fully interconnected with silicate groups, and Q3 indicates that the Q unit is linked in three places (referred to as branching points). (Redrawn from Hiradate, S., and S.-I. Wada. 2005. Weathering processes of volcanic glass to allophane determined by ^{27}Al and ^{29}Si solid-state NMR. Clays Clay Miner. 53:401–408, Fig. 4. With permission of The Clay Minerals Society.)

This process is consistent with modern understanding about the crystal structure of allophane. Its structure is regarded as being based on that of imogolite, another aluminosilicate that is sometimes found (typically in small amounts) in soils derived from tephra and in some other soils including podzols. Imogolite has an ideal chemical formula of $SiO_2 \cdot Al_2O_3 \cdot 2H_2O$ and, therefore, an Al:Si ratio of 2:1. The imogolite structure, established by Cradwick et al. (1972), consists of a defect gibbsitic Al-octahedral sheet framework. Si in each silica tetrahedron is attached to this framework by sharing three of its O atoms (hence the Q3 notation shown in Figure 20.5) with an octahedrally coordinated Al on the gibbsitic sheet while the remaining O atom on the tetrahedrally coordinated Si acquires an H atom to form a Si–OH bond pointing away from the gibbsitic sheet. Although imogolite, which comprises long, thin hollow nanotubes, always in bundles, has a definite XRD pattern (Yoshinaga and Aomine, 1962), and, hence, some long-range order, allophane gives extremely broad, low-intensity humps in XRD and is regarded as a mineral with short-range order (SRO), or a poorly ordered aluminosilicate, as well as a "structured nanomineral" (Hochella, 2008; Theng and Yuan, 2008; McDaniel et al., Section 33.3). The best term for it is "nanocrystalline," meaning structured at the nanometer scale, that is, 1–100 nm. (Another nanocrystalline mineral that occurs commonly but usually in relatively small amounts in weathered tephras and other materials, and which is analogous to allophane, is ferrihydrite, described later herein.) Allophane composition varies over a much greater range than that of imogolite, although morphologically all unit particles

comprise tiny hollow spherules or "nanoballs" (Parfitt, 2009). In soils, there are two main types: (1) Al-rich, with Al:Si ~ 2:1—these are imogolite-like or proto-imogolite allophanes—and (2) Si-rich, with Al:Si ~ 1:1—these are halloysite-like allophanes. The imogolite-like nanocrystalline structure applies only to Al-rich allophane, which is the most common type (Parfitt, 2009). Generally, it has an XRD pattern that is often indefinite, even if distinct peaks appear for some samples (Parfitt, 1990), but the pattern is likely to be indistinct when allophane is associated with long-range-ordered crystalline minerals. Therefore, a number of other sophisticated instrumental methods have been proposed for its identification. Earlier, these included infrared spectroscopy, differential thermal analysis, and TEM (Fieldes, 1955). More recently, electron diffraction (Wada and Yoshinaga, 1969), small-angle neutron scattering (Hall et al., 1985), ^{27}Al and ^{29}Si NMR (Goodman et al., 1985; Hiradate and Wada, 2005; Hiradate et al., 2006), and XPS (He et al., 2008) have also been used. Yet, it is a chemical method, for the extraction of Al and Si, among other metals, using acidified ammonium oxalate and developed long ago by Tamm (1922), which has become the standard (and critically important) procedure for both identifying and quantifying allophane (Parfitt and Henmi, 1980; Parfitt and Wilson, 1985; Wada, 1987, 1989).

Halloysite often also forms by the weathering of tephra. Although halloysite, as a 1:1 Si:Al mineral with the same aluminosilicate composition as kaolinite, has often been identified by a peculiar shape in electron micrographs (see Section 20.3.2), it is only the occurrence, or else evidence for prior occurrence, of interlayer water that distinguishes halloysites unequivocally from kaolinites (Churchman and Carr, 1975; Churchman, 2000). With the knowledge that allophane is a fast-forming SRO (nanocrystalline) product from the dissolution mainly of glass whereas halloysites, being crystalline with long-range order, generally give distinct peaks in XRD, there has been much debate over the question of whether allophane alters to halloysite and, if so, how this change occurs. There have been two main schools of thought regarding this question. One of these, proposed by Fieldes (1955) and which was the predominant idea until around the 1980s, held that allophane altered to halloysite with the passage of time. This mineralogical change was considered to occur by a solid-phase transformation involving dehydration and "crystallization" from an "amorphous" material.

According to the alternative view, which was formulated in Parfitt et al. (1983) and subsequent papers (e.g., Parfitt et al., 1984; Parfitt, 1990, 2009), it is the concentration of Si in soil solutions [Si], and availability of Al, which largely determine the nature of the aluminosilicate secondary minerals that form from volcanic parent materials by weathering. In particular, allophane is favored by a lower [Si], whereas halloysite tends to result when [Si] is relatively high. This theory was based on mineralogical and soil solution data from a rainfall sequence of soils formed on tephra-derived deposits in northern New Zealand. It was supported by Singleton et al. (1989) who measured in detail modern solution [Si] in soils forming a drainage sequence on tephric materials of similar composition and age.

Parfitt's theory helped to explain some anomalies concerning the application of Fieldes' (1955) hitherto pervasive theory that allophane seemed to inevitably alter or "transform" to halloysite with time. Fieldes' theory was based on the worldwide recognition that halloysite tended to occur at depth in many tephra-derived soil sequences whereas allophane predominated in surface horizons. Because such sequences become stratigraphically older with increasing depth, the assumption was made that allophane formed first and then, after ca. 10,000–15,000 years, it apparently transformed to halloysite (see review by Lowe, 1986). However, in northern New Zealand, McIntosh (1979) showed that authigenic halloysite (both spheroidal and tubular) had formed by recent processes in tephra deposits only ~1800 years old. He demonstrated that such halloysite formation was a consequence of resilication from a Si-rich soil solution—the resilication was indicated by Si:Al ratios of ~2 at depths of ≥ 2 m, in contrast to values of ≤1 in surface horizons, and by modern lysimeter leachate compositions (McIntosh, 1980). Other reports had previously demonstrated the seemingly "anomalous" occurrence of halloysite in young soils (Hay, 1960; Bates, 1962; Bleeker and Parfitt, 1974), and electron micrographs showed a close association of halloysite with the surfaces of parent minerals/mineraloids, both glass (Dixon and McKee, 1974) and feldspars (Tazaki, 1979; see Lowe, 1986, and also Figure 20.3 herein). Similarly, Ogura et al. (2008) showed in recent, proximal scoriaceous tephras (deposited since AD 800) near Mt. Fuji, Japan, that the coarse particle sizes and large pores facilitated rapid drying, aiding the concentration of Si and hence neoformation of tiny spherical halloysite particles. Thus, it became clear that halloysite, rather than allophane, was able to form directly from tephra materials in young soils under certain conditions where [Si] was relatively high. In reality, [Si] may vary seasonally, and kinetic considerations can lead to the formation of halloysite if the periods of high [Si] greatly exceed those when [Si] is low. The use of oxygen isotopes to trace the temperature of formation of minerals, among other techniques, led Ziegler et al. (2003) to conclude that halloysite has formed continuously from the early stages of formation from basalt in an arid zone in Hawaii as the result of prolonged extremely dry seasons following short periods of intense rainfall. The release of Al in the latter had been followed by a prolonged buildup of Si and hence halloysite formation. In addition, it had long been known that allophane was present in some very old weathered-tephra sequences (Ward, 1967; Tonkin, 1970), which had always been a puzzle in view of the Fieldes' model (although the amounts of allophane were not well quantified at that time). A key study was that by Stevens and Vucetich (1985) who used ammonium oxalate dissolution methods to quantify allophane content in a 10 m high tephra weathering sequence in northern New Zealand dating back ca. 350,000 years (the basal tephra being reidentified more recently as the Rangitawa tephra: Lowe et al., 2001). They demonstrated unequivocally that abundant allophane was present in many beds in the sequence. Moreover, through tephrochronology, Stevens and Vucetich (1985) were able to show that allophane (as well as subordinate gibbsite) was predominant during warm,

wet interglacial periods but that halloysite predominated during cool, dry glacial periods, implying that changing environmental conditions had led to changing [Si] and hence different clays. A similar finding was recorded by Bakker et al. (1996). Thus, the weathering of tephra followed separate pathways leading to the formation either of allophane or halloysite, rather than following a single pathway governed by time (Lowe, 1986).

The idea that a high [Si] favored halloysite also made sense of reports of the formation of halloysite instead of allophane when there was a thick overburden (Mejia et al., 1968; Aomine and Mizota, 1973; Wada, 1987; Cronin et al., 1996), and also where drainage was impeded or poor (Aomine and Wada, 1962; Dudas and Harward, 1975; Stevens and Vucetich, 1985; Cronin et al., 1996). Both these situations would give rise to a buildup of Si that, it was then thought, would react with preformed allophane to form halloysite (Aomine and Wada, 1962; Dudas and Harward, 1975; Saigusa et al., 1978).

Zehetner et al. (2003), in Andean Ecuador, Rasmussen et al. (2007), in the Sierra Nevada in California, and Chadwick et al. (2003), on Kohala Mountain in Hawaii, studied the mineralogy of soils formed at different altitudes but from a common volcanic source (andesitic/dacitic ash, andesitic lahar, and basaltic lava, respectively). In each case, it was found that allophane (with imogolite and ferrihydrite in Hawaii) was dominant in soils at higher altitudes and halloysite in soils at lower altitudes, confirming the trends discovered by Nizeyimana et al. (1997) in a similar study on volcanic materials in Rwanda. At higher altitudes, the precipitation is greater; hence, leaching is stronger, solution [Si] is lower, and allophane prevails in the soils formed there. Conversely, precipitation and degree of leaching are lower, and [Si] in solution is higher, at lower altitudes and so halloysite dominates in these soils. Chadwick et al. (2003) emphasized in their Hawaiian study, however, that as moisture increased along the sampling transect, different sets of secondary minerals were favored in response to conditions controlled by arid conditions, by rapid and intense cycles of wetting and drying, or by essentially continuously wet conditions. They developed a leaching index as the ratio of water balance to the integrated porosity of the top meter of soil on an annual basis. The index reached 1 (total filling of the pore space each year) where the mean annual precipitation (MAP) was ~1400 mm. Index values >1 indicated intense leaching conditions because of pore water replacement; leaching losses of soluble base cations and Si were nearly complete at such index values, whereas only 60% of Al had been lost. Where index values were <1, leaching losses were progressively lower with the lowest rainfall sites having lost 10%–20% of the original base cations and Si, but none of the Al.

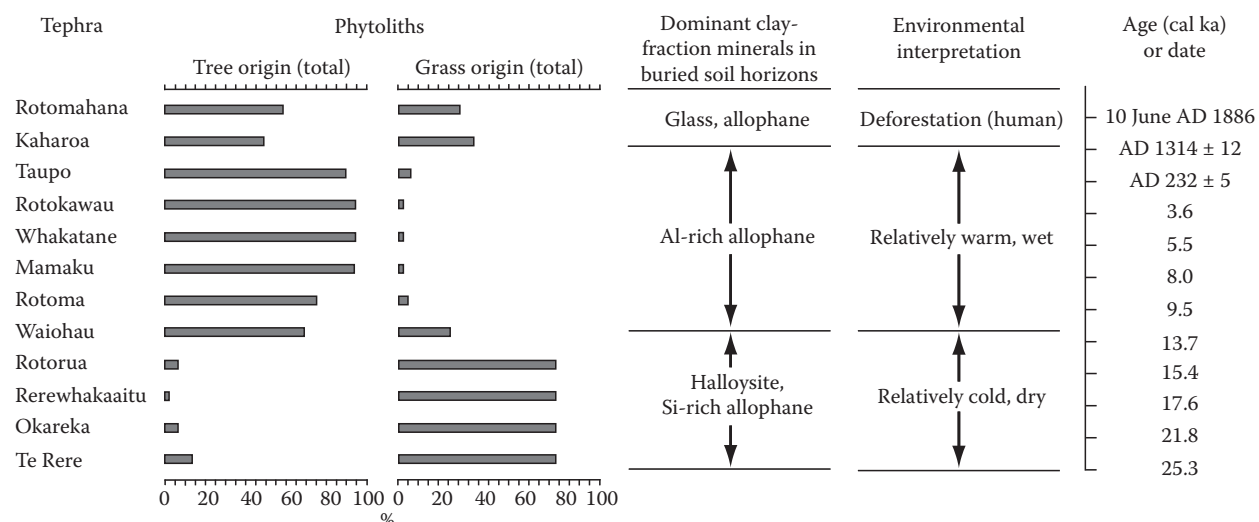
Rasmussen et al. (2007) found further that soils in intermediate zones of altitude contained both allophane and halloysite and also that soils at extremely high altitudes had neither allophane nor halloysite but instead were dominated by interlayered 2:1 Si:Al layer silicates, which they considered to be inherited from the parent material. These authors considered that climate controlled the clay minerals formed from the volcanic materials. Rainfall explained the secondary phases formed except at the


FIGURE 20.6 Dominant clay minerals and phytoliths identified in buried soil horizons in a sequence of 11 rhyolitic tephras and one basaltic tephra (Rotokawau) deposited near Rotorua, New Zealand, since ~25,000 calendar (cal) years ago showing the relationship between the clay mineral assemblages and environment (based on Green, 1987; Sase et al., 1988; Lowe and Percival, 1993; Kondo et al., 1994). ka, thousands of years before present. Dates for Kaharoa and Taupo eruptions are from Hogg et al. (2003, 2011); other ages are from Lowe et al. (2008). (Modified after Newnham, R.M., D.J. Lowe, and P.W. Williams. 1999. Quaternary environmental change in New Zealand: A review. Prog. Phys. Geog. 23:567–610. With permission of SAGE Publications.)

higher, colder sites, where temperature inhibited mineral alteration and the formation of new mineral phases. These altitudinal (hence rainfall) studies have further demonstrated the validity of Parfitt et al.'s (1983) model for the effect of [Si] in controlling the formation of secondary minerals from the weathering of volcanic parent materials (where Al availability effectively is unlimited). Further evidence for the validity of this model was demonstrated in a succession of buried soil horizons formed on rhyolitic tephras dating back ~25,000 years near Rotorua in New Zealand (Figure 20.6; Newnham et al., 1999). Cold and dry conditions and grassland vegetation before ~13,000 years ago resulted in halloysite (with minor Si-rich allophane) being formed because of limited Si leaching under lowered rainfall. Al-rich allophane was formed after ~13,000 years ago when Si loss increased through stronger leaching as rainfall and temperatures increased and forest replaced the grassland. In addition, halloysite formation was likely enhanced through enrichment by SiO_2 in leachates carried down the section as the tephras accumulated above, and by a concomitant reduction in permeability in the halloysitic horizons, which have a greater bulk density (Parfitt et al., 1983; Bakker et al., 1996). The paleoenvironmental interpretation was established by analyses of phytoliths (siliceous plant cell remains) at the same site together with palynological and other evidence from sites elsewhere in the region (Sase et al., 1988; Kondo et al., 1994; Newnham et al., 1999). A similar conclusion was reached in a parallel study in Mexico (Sedov et al., 2003).

The model was further supported by a study of seven pedons within the caldera of a volcano in Italy, which showed that the secondary minerals reflected the hydraulic properties, namely, drainage, of the parent materials (Vacca et al., 2003). In this case,

allophane had formed in soils developed in younger, porous, permeable ash deposits, while soils formed in older, less porous and less permeable scoria and consolidated tuffs contained crystalline minerals, especially halloysite, but no allophane.

Other aluminosilicate minerals can also form from volcanic parent materials by weathering. Possible products include 2:1 Si:Al aluminosilicates, which are most likely to occur where biotite is present as a product of the transformation of this mineral through the replacement of interlayer potassium ions, most probably by hydrated divalent cations (see Section 20.2.4.3). Various workers in the past (reviewed by Lowe, 1986) have proposed that a wide variety of 2:1 Si:Al aluminosilicates have formed in soils from volcanic parent materials, including volcanic glass, but several more recent publications (e.g., Nieuwenhuyse et al., 2000; Kautz and Ryan, 2003; Mirabella et al., 2005; Rasmussen et al., 2007) have confirmed that these types of phyllosilicates, including illite, smectite, vermiculite, chlorite, kaolinite, and their interstratifications with one another, may be inherited either from the parent pyroclastic material, where they may have formed by hydrothermal processes prior to weathering, or else as a contaminant of other, nonvolcanic origin such as aeolian dust.

Nonetheless, some aluminosilicate, and also more aluminous minerals, do form from volcanic parent materials either alongside, or instead of, allophane and halloysite (Theng et al., 1982). Parfitt et al. (1983) noted that gibbsite was recognized in a 1968 report as a product of the weathering of volcanic ash that was deposited in root channels in soils from Japan while it has also been found to occur in the weathering products of volcaniclastic materials in northern California that have rhyolitic, andesitic, and basaltic inputs (Takahashi et al., 1993). In these latter soils, gibbsite occurs alongside imogolite (or imogolite-like 2:1 Al:Si

allophane) and also halloysite. This concurrence suggests that gibbsite formation may occur during the wet season (winter and early spring) of the Mediterranean (or xeric) climate in northern California, while, as soils dry out in the approach to summer (the dry season), first imogolite/allophane, and then halloysite, is formed. In humid tropical conditions in Cameroon, the occurrence of minor gibbsite in a soil developed on hydrothermally altered nephenelitic materials (Si-poor, alkali-rich lavas) was attributed to the development of a strongly developed microporosity that facilitated the elimination of silica through leaching (Etame et al., 2009).

There appears to be an annual cycle among the secondary minerals resulting from the continually dissolving volcanic parent materials, particularly glass. Fieldes (1968) had proposed that halloysite formation occurred from allophane precursors as a result of seasonal drying (a process invoked also by Chadwick et al., 2003, whereby rapid wetting and drying cycles in arid zones were said to destabilize allophane, forcing it to "dewater and transform into halloysite"). Lilienfein et al. (2003) studied a chronosequence of quite young soils on andesitic mudflows in northern California nearby those in Takahashi et al.'s (1993) study and found that the amount of allophane increased linearly and quite rapidly in soils up to 600 years of age, although the oldest of these soils had less than half as much allophane as those studied by Takahashi et al. (1993) and hence were probably less well developed than the latter soils. Lilienfein et al. (2003) did not record any gibbsite in their soils.

By contrast, Nieuwenhuyse et al. (2000), who also studied a chronosequence on andesitic parent materials (lava, in this case) but in a humid tropical climate in Costa Rica, found all of allophane, kaolin minerals—kaolinite and halloysite—and gibbsite (as well as Al- and Fe-humus complexes and ferrihydrite) in soils from all ages of the parent lavas, ranging from 2,000 to ~450,000 years. Currently, mean monthly precipitation exceeds potential evaporation every month of the year in the present climate for these soils, so there is no dry season to explain the possible formation of relatively Si-rich kaolin minerals along with Si-free gibbsite and Si-poor (i.e., Al-rich) allophane. To explain the simultaneous appearance of these different minerals, Nieuwenhuyse et al. (2000), like Newnham et al. (1999), pointed to palynological evidence of a past drier climate, which evidently occurred in this region around the last glacial maximum. This drier climate, as at Rotorua in New Zealand (Figure 20.6), would have enabled Si-rich halloysite to form at that time, and some of it, at least, has persisted into the current strong leaching regime, with an average annual precipitation of 4500 mm year^{-1}. Nieuwenhuyse et al. (2000) proposed that gibbsite is formed in the soils as a result of the disintegration of the kaolin minerals under strong leaching. This mechanism explains the dominance of gibbsite among secondary minerals after 450,000 years of soil formation. By way of contrast, Certini et al. (2006) found that soils formed from 200,000 year old trachyandesite pyroclastic materials in Italy showed only well-formed gibbsite and an "embryonic" halloysite in their clay fractions. These authors

considered that both are products of the early stages of weathering of volcanic glass. In a hot, wet (perudic) climate in Guadeloupe similar to those studied by Nieuwenhuyse et al. (2000), Ndayiragije and Delvaux (2003) found that gibbsite, allophane, kaolinite, and hydroxyl-Al-interlayered smectite/vermiculite coexisted in a soil from andesitic–dacitic ash, but there was no halloysite in this soil. This soil appears to be similar mineralogically to those studied by Nieuwenhuyse et al. (2000), which occurs in a similar climate, except for the hydroxy-Al 2:1 Si:Al aluminosilicate. This last mineral was seen by Ndayiragije and Delvaux (2003) as an inheritance from the parent tephra and its aluminous interlayers were regarded as performing an antigibbsite (Jackson, 1963) or analogous antiallophane effect by preferentially sequestering Al, at least until the available interlayers became saturated.

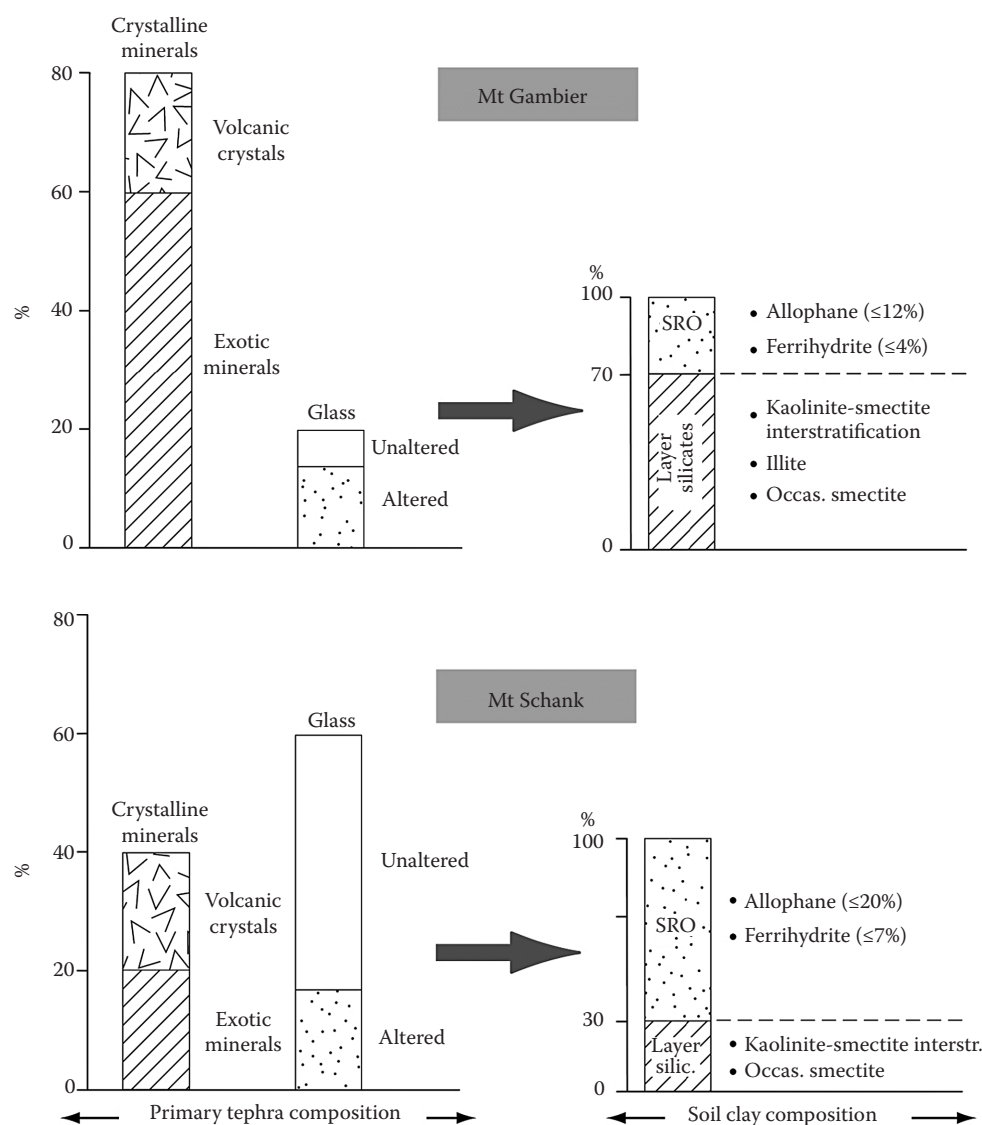
Although activity of Si is clearly critically important in governing the formation of halloysite, allophane, or gibbsite in soils from volcanic parent materials (especially tephra) (see, e.g., a stability diagram for these minerals in Churchman, 2000, Figure 1.11), there may also be competitors for Al, such as hydroxyl-Al-interlayered smectite/vermiculite, as discussed by Ndayiragije and Delvaux (2003) (see also Kleber et al., 2007). Quite often competition for Al also arises from organic matter (especially large quantities are derived from, e.g., pampas grass *Miscanthus sinensis* in Japan), which gives rise to fast-forming, resistant Al-humus complexes in soils with pH < 5 (Shoji et al., 1993a; Dahlgren et al., 2004; Hiradate et al., 2004; Parfitt, 2009). Carboxyl groups of humic materials and the 2:1 layer silicates effectively compete for dissolved Al, leaving little Al available for coprecipitation with Si to form allophane or imogolite (Dahlgren et al., 2004; Theng and Yuan, 2008). The preferential incorporation of Al into Al-humus complexes, as with hydroxyl-Al interlayers of 2:1 layer silicates as noted above, is another example of the "antiallophane" effect (McDaniel et al., Section 33.3). Thus, preformed allophane disintegrated and was replaced by Al-humus after only 30 years under bracken fern, consistent with a fall in pH from 5.2 to 4.6 (Johnson-Maynard et al., 1997). Furthermore, weathering of tephra from the 1980 eruption of Mt. St. Helens led to Al-humus and also hydroxy-Al interlayers in 2:1 Si:Al aluminosilicates rather than to any of allophane, imogolite, or opaline silica (Dahlgren et al., 1997). However, opaline silica can form alongside Al-humus complexes, and Fe may also become incorporated into complexes with humus (Wada, 1989). Recent studies in Ecuador (Poulenard et al., 2003) and Japan (Yagasaki et al., 2006) have shown, respectively, that Al-humus complexes form rather than allophane when the content of organic C is particularly high or that allophane is dissolved in favor of Al-humus complexes when organic C content increases. As well, Al-humus complexing predominates at sites more distal to volcanoes because such sites infrequently receive a "top up" of Al through the deposition of weatherable tephras in comparison with sites closer to volcanic sources that are more regularly dusted with tephra.


FIGURE 20.7 Contrasts in sand mineral assemblages of soils on mid-Holocene basaltic tephra erupted from Mt. Gambier and nearby Mt. Schank in South Australia have led to markedly different soil clay compositions under a xeric moisture regime. SRO, short-range order (i.e., nanocrystalline); interstr., interstratification; occas., occasional. (Modified after Lowe, D.J., and D.J. Palmer. 2005. Andisols of New Zealand and Australia. J. Integr. Field Sci. 2:39–65. With permission of Tohoku University.)

A variety of secondary minerals could be found in soils developed in the erupted material from the basaltic volcanoes at Mts. Gambier and Schank in southeast South Australia, which are only 10 km apart and both about 5000 years old (Lowe et al., 1996; Lowe and Palmer, 2005; Takesako et al., 2010). The main types of clay minerals formed in a xeric moisture regime with a relatively low average annual precipitation of 700 mm are shown for each location in Figure 20.7. They are compared with the categories of primary minerals in the parent materials, which comprise both volcanic and nonvolcanic "exotic" minerals incorporated into the eruptives from underlying calcareous sands and limestone. There is a contrast between the clays found at or near Mt. Gambier, on the one hand, and Mt. Schank, on the other. The

former are dominated by layer silicate minerals, including interstratifications of kaolinite and smectite, illite, and some discrete smectite. The secondary minerals in soils in the vicinity of Mt. Schank show less variety. They tend to contain more allophane and ferrihydrite than those from the Mt. Gambier area. For the soils from both sites, while both kaolinite–smectite and illite occur in many Australian soils (Norrish and Pickering, 1983; Churchman et al., 1994) and probably do not originate from the recent volcanic material, the discrete smectite found in poorly drained subsoils is probably formed by neogenesis from elements from the dissolution of the basaltic tephra (Lowe et al., 1996; Lowe and Palmer, 2005; Takesako et al., 2010). Notably, there was no halloysite formed in any of the soils at either Mt. Gambier

or Mt. Schank. Allophane showed a range of composition within profiles; its Al:Si ratio determined using acid oxalate-extractable Al (minus organically associated pyrophosphate-extractable Al) as a ratio to acid oxalate-extractable Si was Al:Si ~ 2 in upper parts of the soil profiles but dropped to Al:Si ~ 1 lower in the same profiles (Lowe et al., 1996; Lowe and Palmer, 2005). Lowe et al. (1996) suggested that there had been seasonal leaching during winter and early spring, leading to the formation of Al-rich allophane toward the surface, but weaker leaching (or even slight accumulation of Si) at depth, leaving Si-rich allophane rather than halloysite.

The volume of water draining through the upper part of the profile each year has been measured as about 280 mm, which just exceeds the threshold of about 250 mm for Al-rich allophane to form according to models derived from New Zealand data (Parfitt et al., 1984; Lowe, 1995). Jongmans et al. (1994) also found both Al-rich and Si-rich forms of allophane, respectively, in the B and C horizons, in the same profiles in soils in Guadeloupe. Alloway et al. (1992) similarly found differences in Al:Si ratios (and 15 bar water retention) in upbuilding Andisols in the Taranaki region of North Island, New Zealand, which they attributed to changing

climatic conditions from late glacial to postglacial periods; increasing rainfall and fewer prolonged dry periods resulted in higher Al:Si ratios because of increasing desilication.

Lowe (1986, 1995) and Lowe and Percival (1993) summarized data on the critical conditions for the formation of each of the main products of the weathering of volcanic ash. These are given in Figure 20.8, which also shows if Andisols are likely to have formed, and if they are of the allophanic or Al-humus (nonallophanic) type (McDaniel et al., Section 33.3).

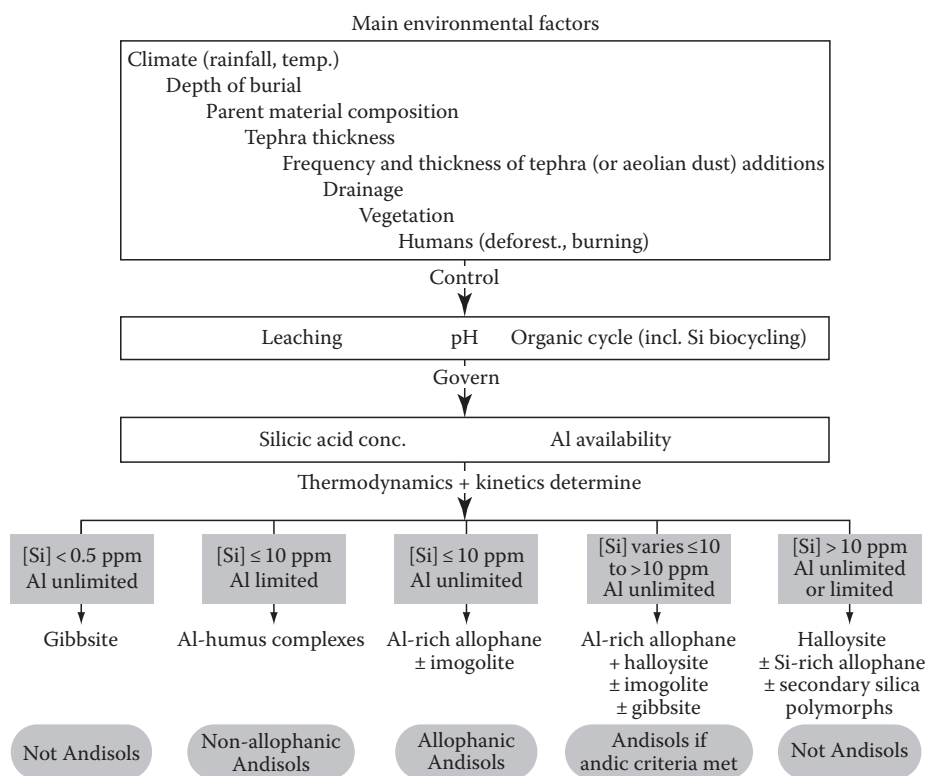
A consideration of rates of chemical processes brings in the question of kinetics. Examples of kinetic studies dealing with the dissolution of glass in tephras and associated soils include those of Hodder et al. (1990, 1996) for rhyolitic tephras, Ruxton (1988), and Neall (1977) for dacitic and andesitic tephras, respectively, and Gislason and Oelkers (2003), Ziegler et al. (2003), Wolff-Boenisch et al. (2004), Shikazono et al. (2005), and Sigfusson et al. (2008) for basaltic tephras or lavas. Generally, basaltic and intermediate (andesitic, dacitic) tephras, with lower Si contents, tend to weather more readily than rhyolitic tephras, but in all cases glasses weather very quickly as noted earlier (Kirkman and McHardy, 1980;


FIGURE 20.8 Environmental influences and controls that govern the critical conditions leading to the formation of different clays from the weathering of tephras, and the likely occurrence or not of Andisols as a result. ± indicates that the clay mentioned may also be present. (Modified after Lowe, D.J. 1986. Controls on the rates of weathering and clay mineral genesis in airfall tephras: A review and New Zealand case study, p. 265–330. *In* S.M. Colman and D.P. Dethier (eds.) Rates of chemical weathering of rocks and minerals. Academic Press, Orlando, FL; Lowe, D.J. 1995. Teaching clays: From ashes to allophane, p. 19–23. *In* G.J. Churchman, R.W. Fitzpatrick, and R.A. Eggleton (eds.) Clays: Controlling the environment. Proc. 10th Int. Clay Conf., 18–23 July 1993, Adelaide, Australia. CSIRO Publishing, Melbourne, Australia.)

Wolff-Boenisch et al., 2004). Compared with hard rock, the fragmental tephra components, especially vesicular glass and pumice, have a much greater surface area and high porosity and permeability, and so break down to constituent compounds very readily (Wolff-Boenisch et al., 2004).

Ziegler et al. (2003) suggested that kinetics controlled the formation of allophane and halloysite in arid soils on the basis of their work on a chronosequence of Hawaiian soils on basaltic lavas (with ash overlying lava in one case) in arid conditions (MAP 180–225 mm). Thermodynamics do not control the composition of soils unless soil solutions remain in contact with the mineral surfaces until equilibrium is reached. Where this does not occur, such as under arid conditions, kinetic factors control the soil system (Ziegler et al., 2003). Clay mineral synthesis in the Hawaiian arid-zone chronosequence was thus shown by Ziegler et al. (2003) to be controlled by the kinetics of soil drying, rather than thermodynamics, so that halloysite was the favored aluminosilicate end product with the formation of smectite inhibited by kinetic factors (and a lack of micas to "fuel" the dominant pathway for smectite formation; Chadwick et al., 2003). In Cameroon, the depth distributions of 0.7 and 1 nm halloysite in soils developed on weathered nephelinite lavas were able to be related to both kinetic and thermodynamic factors by Etame et al. (2009). That Si concentrations increased with depth in the profiles while Al remained relatively constant, and 1 nm halloysite occurred exclusively in lower horizons whereas both 0.7 and 1 nm halloysites were present in upper horizons, led Etame et al. (2009) to two suggestions. First, the 1 nm halloysite formation was controlled by direct precipitation from Si–Al-rich solutions (released from the weathering of primary minerals), and, therefore, the availability of Si was the only factor that controlled its formation at the base of the profile. Second, the presence of both forms of halloysite in the upper parts of the profiles implied that kinetics, hence time, controlled the evolution of halloysite through wet–dry seasonality, aided by the thermodynamically favorable factor of the availability of Si (Etame et al., 2009). In tropical Costa Rica, the predominance of 1.0 nm over 0.7 nm halloysite in the wetter, lower subsoil horizons of profiles studied by Kleber et al. (2007) was attributed to Si enrichment by percolating waters (i.e., mainly for kinetic reasons).

Returning to the question of whether it is time (Fieldes, 1955) or solution concentration/activity, particularly of Si (Parfitt et al., 1983, 1984), that governs whether or not allophane or halloysite persists in soils from volcanic parent materials (leaving aside Al-humus complexing), it may be said that while the evidence is very strongly in favor of solution conditions determining the nature of the minerals formed, the passage of time also appears to enhance halloysite formation at the expense of allophane via the so-called Ostwald ripening process (e.g., Chadwick and Chorover, 2001; Dahlgren et al., 2004; Rasmussen et al., 2007). This direction of change is consistent with the thermodynamic stabilities of the two mineral types (see, e.g., Figure 1.11 in Churchman, 2000). Structural considerations, however, mean

that an Al-rich allophane, with isolated tetrahedra on the inside of a spherule of coiled gibbsite-like sheets, cannot transform in the solid state into halloysite, where sheets of linked silica tetrahedra are generally coiled around alumina octahedra and hence are in the opposite conformation one to each other as in the allophane spherule. Therefore, dissolution and recrystallization must be involved in the change from allophane to halloysite. Nonetheless, it is likely that the passage of time effects other changes, which affect the environment in which mineral alteration and formation take place, so that conditions that favor the formation of allophane early in the weathering process change to those favoring halloysite formation. Most often in upbuilding terrains, this comes about through an increase in [Si], which may result from a buildup of overburden through ongoing tephra deposition, or the development of impediments to efficient drainage (e.g., Cronin et al., 1996). Another possible change may be toward a drier climate, so that there is less throughflow of water and hence a buildup of Si in solution. An alternative situation is that reported by Chadwick and Chorover (2001) for a Hawaiian chronosequence on basaltic lavas and ash deposits not subject to ongoing burial by later eruptives. There, the ongoing depletion of [Si] and increase in [H^+] under high rainfall after ca. 400,000 years eventually led to the formation of more stable kaolin (halloysite and kaolinite) and gibbsite. Previously, conditions had apparently favored the formation of allophane. Chadwick and Chorover (2001) noted that [Al] in solution also declined over time, a result that follows from increasing crystallinity and decreasing solubility of gibbsite and kaolin in the soil. Inconsistencies between observed soil mineral composition and stability-field plots of solution chemistry data are evidence of kinetic limitations to mineral transformations according to Chadwick and Chorover (2001), who also noted that such discrepancies can be resolved through consideration of mineral transformation rates and Ostwald ripening processes but that the requisite kinetic data are often lacking.

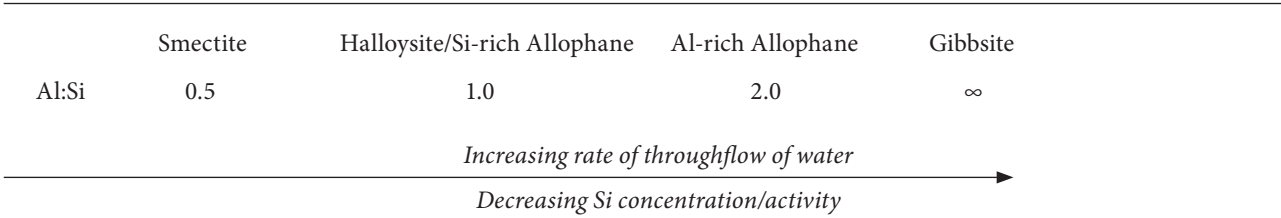
In considering longer timescales of glacial and interglacial cycles in temperate volcanic landscapes not directly glacierized, the marine oxygen isotope records show that cooler and drier conditions associated with glaciations persisted ~80%–90% of the time whereas warmer and wetter conditions associated with interglaciations occurred for ~10% to 20% of the time. In these landscapes, where long sequences are well preserved, therefore, it might be expected that soils developed from accumulations of weathered tephras of similar composition dating back several hundreds of thousands of years to one or two millions of years should be dominated by halloysite rather than allophane (e.g., as evident in the so-called Kauroa and Hamilton ash tephra sequences in northern New Zealand that date back to ca. 2.3 Ma; Lowe and Percival, 1993; Lowe et al., 2001).

Overall, the relationship between the minerals formed from volcanic parent materials (especially tephra) and solution [Si], as it is affected by the throughflow of water and given appropriate kinetic circumstances, can be expressed by Box 20.3:

Box 20.3   Relationship between Throughflow of Water, Si Concentration, and Types of Clays Formed from Volcanic Parent Materials

	Smectite	Halloysite/Si-rich Allophane	Al-rich Allophane	Gibbsite
Al:Si	0.5	1.0	2.0	∞

Increasing rate of throughflow of water →

Decreasing Si concentration/activity


We note in addition that allophane can be formed in a range of nonvolcanic materials through strong leaching and acid conditions, as occur, for example, in loess in upland areas of southern New Zealand (e.g., Eger and Hewitt, 2008), and as a result of podzolization (see Section 20.2.5.3.2).

Parallel to the alteration of aluminosilicate minerals and the formation of allophane, halloysite, and perhaps also gibbsite or smectites, iron is also lost from parent Fe-bearing minerals and incorporated into secondary solid phases. Ferrihydrite forms early in the process of weathering of volcanic parent materials from the precipitation and oxidation to Fe(III) of soluble Fe(II) that had been released into solution from volcanic glass and also feldspars and mafic minerals (e.g., McDaniel et al., Section 33.3). It is the presence of other species in solution such as silicate and phosphate ions and soluble organic compounds that inhibit the formation of the more crystalline forms of iron, such as goethite and hematite (e.g., Childs, 1992; Bigham et al., 2002). However, the type of iron oxide that is formed is a function of the same environmental conditions that also affect which particular aluminosilicates are formed in volcanogenic soils. Hence, in young soils on andesitic mudflows, the buildup of ferrihydrite with time paralleled that of allophane, albeit that the amount of allophane formed was ~10 times or more than that of ferrihydrite (Lilienfein et al., 2003). In a chronosequence of soils in the humid tropics, Nieuwenhuyse et al. (2000) found that Fe occurred mainly as Fe-humus in the two younger soils, especially in their A horizons, but also as ferrihydrite, especially at depth, whereas it occurred mainly as goethite throughout the oldest soil in the sequence. Further, the iron oxides in soils in a xeric moisture regime that contain all of gibbsite, imogolite and/or Al-rich allophane, and halloysite as aluminosilicates were dominantly highly crystalline—they were mainly goethite, reflecting strong seasonal drying (Takahashi et al., 1993). Soils in a toposequence on andesitic lahar deposits covering a range of climatic zones generally showed a similar pattern to that for the aluminosilicates, with poorly crystalline forms giving a high oxalate-Fe analysis dominant in soils at higher altitudes and more crystalline forms giving a high dithionite-Fe analysis in soils at lower altitudes (Rasmussen et al., 2007). There was a further subtlety with Fe analyses, however, insofar as the proportion of oxalate-Fe to dithionite-Fe rose again at the lowest altitude, where the MAP was also lowest. In this drier zone, less leaching probably led to higher retention of Si in soil solution, which would inhibit Fe oxide crystallization (Rasmussen et al., 2007).

20.2.4.6.3 *The Special Case of "Palagonite"*

In the volcanic and geochemical literature especially, the term "palagonite" is widely used to describe the first stable product of basaltic volcanic glass alteration (e.g., Fisher and Schminke, 1984; Cas and Wright, 1987; Daux et al., 1994). Palagonite has also been described in the clay science literature but uncommonly (e.g., Singer and Banin, 1990; Drief and Schiffman, 2004) and it thus deserves some attention here. As reviewed by Stroncik and Schmincke (2002), palagonite (named after the location Palagonia in Sicily) is a heterogeneous substance, usually with highly variable optical and structural properties ranging from a clear, transparent, isotropic, smooth, and often concentrically banded material, commonly called "gel-palagonite," to a translucent, anisotropic, slightly to strongly birefringent material of fibrous, lath-like, or granular structure, commonly called "fibro-palagonite." It ranges in color from yellowish to shades of brown. Since it was first defined in 1845 as a new mineral, palagonite has been interpreted in numerous studies to be a heterogeneous material composed variously of different aluminosilicate clays, zeolites, and oxides, or mixtures of these. Based on XRD, HRTEM, atomic force microscopy (AFM), and electron microprobe analyses, palagonite is now interpreted by most to be composed of a variety of smectites and very minor amounts, if any, of zeolites and oxides (Stroncik and Schmincke, 2002). At more advanced stages of alteration, other secondary phases are known to form following Ostwald "ripening" processes.

Palagonite evidently comprises spherical structures 20–60 nm in diameter, which have been interpreted as "microcrystallite precursors of smectite" (Stroncik and Schmincke, 2002)—that is, palagonite would seem to be a nanocrystalline variety of smectite(s). Drief and Schiffman (2004) identified an Fe-rich montmorillonite-like composition in their study on Hawaiian basaltic deposits. The atomic structure of palagonite and, especially, its structural evolution are not yet fully understood, but both are important to glass-alteration rates and to the evolution of the whole water–rock–soil system (Stroncik and Schmincke, 2001). Because kinetic and thermodynamic modeling and mass–balance calculations necessitate exact differentiation of all the secondary products developing during alteration, the term "palagonite" should be used only for the hydrous nanocrystalline alteration product ("gel-palagonite"), not for the long-range-ordered crystalline material evolving from the palagonite itself (Stroncik and Schmincke, 2001, 2002).

The so-called palagonitization of basaltic volcanic glass is a continuous process of glass dissolution and palagonite formation and evolution, which, according to Stroncik and Schmincke (2001), can be subdivided into two different reaction stages with changing element mobilities. Stage 1 is the congruent hydration and dissolution of thermodynamically unstable glass and contemporaneous precipitation of "fresh," gel-like, amorphous (or nanocrystalline), optically isotropic, mainly yellowish palagonite. This stage, kinetically controlled and consistent with the models of Hodder et al. (1990, 1993), is accompanied by the loss of Si, Al, Mg, Ca, Na, and K, active enrichment (gain) of H_2O, and the passive enrichment ("default" accumulation relative to other elements) of Ti and Fe. Stage 2 is an aging process during which the thermodynamically unstable palagonite reacts with the surrounding fluid and crystallizes to smectite. This stage is accompanied by uptake of Si, Al, Mg, and K from solution and the loss of Ti and H_2O. Ca and Na are still showing losses, whereas Fe reacts less consistently, remaining either unchanged or showing losses (Stroncik and Schmincke, 2001, 2002).

20.2.5 Peculiarities of Processes and Products of Alteration by Weathering in Soils

Much—although not all—of the information on the processes and products of alteration of primary minerals by weathering that is summarized in the preceding Section 20.2.4 comes from observations of rocks or geological deposits, minerals associated with these materials, and saprolites deep within soil profiles. However, soil profiles can encompass a range of conditions, from fragmented, almost abiotic, rock through to organic-rich material containing a great variety of microbial, faunal, and also plant life. The different parts of soil profiles represent different regimes for water, from abundant and mobile to scarce and largely immobile, so studies of some nonsoil situations where each of these prevail are relevant to weathering in some parts of soils but not in others. Most soils have a significant biological input, at least in their surface layers, and, therefore, the biological factor in mineral alteration and formation tends to play a larger role in

the genesis of soil minerals than in those from rocks subject to largely abiotic weathering. Furthermore, some processes, notably podzolization, occur within permeable soils but not in impermeable rocks under certain environmental conditions and deserve particular attention. In addition, soils can be further developed even following the depletion of easily weatherable rock-derived minerals. Secondary minerals can themselves be altered and new phases formed. Each of these particular aspects of mineral development in soils will be discussed in the following sections.

20.2.5.1 The Effect of Position within Soil Profiles on Hard Rock

In a recent review, Wilson (2004) showed that position in the weathering profile on indurated rock has a crucial influence on the nature of the environment for weathering and hence on the processes involved and products formed, as well as the rates at which changes occur. Note that modified models are required for soils formed on unconsolidated materials or, especially, those developed through upbuilding pedogenesis. Following Delvigne (1998), a fully developed weathering profile comprises a soil, which is delineated (in a straightforward case) into A and B horizons (solum) and usually C or CR horizons comprising saprolite/alterite, which consists of completely disaggregated rock grading to the rock base, with fabric and texture changing with depth. At the base of the whole profile is the (partly) weathered rock (R horizon), which may be hard and coherent but also incorporates fractures and fissures. Among other features, an increase in surface area characterizes the upward change from the rock to the solum (Hochella and Banfield, 1995).

There is also a trend of decreasing porosity and permeability from soil down to rock, so that water can flow quite freely within the soil, but can be either stagnant or held in capillaries in the rock. Hence, there is a much greater chance of an equilibrium being established between the minerals and the largely immobile solution within the rock than between the minerals and the highly dynamic water in the soils zone.

Following Velde and Meunier (2008), we note that alteration within the rock proceeds in microsystems. Meunier and Velde (1979) followed the alteration of granites by weathering through developments occurring at the scale of microsites. The system is highly heterogeneous at this fine scale; grains of the primary minerals, muscovite, orthoclase, and biotite each give rise to multiphase assemblages upon alteration. Alteration of the whole mineral assemblage appears to take place in three stages. In the first stage, alkalis are lost but the Si:Al ratio is preserved as illitic mica, beidellite, and vermiculite are variously formed. The second stage involves a loss of both alkalis and silica with kaolinite and oxides resulting. The authors surmised that there is a third stage where quartz is dissolved, leaving only oxides, but not silica. This last stage is seen in tropical weathering. The processes of in situ alteration of ferromagnesian minerals to smectites and of feldspars to illite that were studied by Eggleton and coworkers and Banfield and coworkers, among others, and cited in Section 20.2.4 herein, also occur within microsites where the physical constraints as well as the chemical availability of reagents limit the reactions that

can take place. In a particularly close study of microsites within one mineral type (amphibole) on weathering, Proust et al. (2006) found that montmorillonite formed on the (001) amphibole face and saponite on the (110) face, while the sawtooth (001) face fracture surface hosted a kaolinite–smectite and, with time, also halloysite and montmorillonite. The establishment of local equilibria may occur at different sites, within both a single crystal, as in the amphibole studied by Proust et al. (2006), and also within different fractures and fissures in a rock (see the diagrammatic representation for granite in Figure 4.19 of Velde and Meunier, 2008). Within microsites where secondary products remain in close proximity to host primary minerals, reactions may even occur between product and host minerals (Velde and Meunier, 2008). As a result, vermiculite may form by recrystallization in a microsite from the dissolution products of the adjacent secondary minerals, saponite or Fe–beidellite and their primary precursor, amphibole for one example (Velde and Meunier, 2008). For another example (Velde and Meunier, 2008), product smectite and host K-feldspar may react together to give rise to illite and kaolinite.

The solid:solution ratio is very high in hard rocks that remain coherent yet contain small fractures and fissures. By great contrast, the solid:solution ratio in the solum or unconsolidated geological deposits within the weathering profile is likely to be both very low and quite variable on both a daily and seasonal basis, except in special circumstances, for example, in a desert or frozen soil. The dynamic nature of soils alone ensures that the possibility of predicting the course of weathering via stability diagrams for the component clay minerals (e.g., Kittrick, 1967) cannot be realized. Minerals awash in the dynamic water phase in soils almost certainly remain well out of equilibrium with those solutions (Chadwick and Chorover, 2001; Wilson, 2004). However, those formed in microsites within weathering rocks deeper in the weathering profile may not appear in bulk analyses of soils above the weathering rock. In particular, trioctahedral smectites formed during early stages of alteration are rarely reported in soils. Either they are unstable in the soil environment (Wilson, 2004) or they are present in only vanishingly small concentrations (Proust et al., 2006), or both.

20.2.5.2 Weathering in the Absence or Shortfalls of Water

Generally on Earth, weathering occurs because there is sufficient—and usually excess—water to effect alteration of primary minerals and either transformation to related secondary phases or neogenesis of new (secondary) minerals. However, mineral alteration and formation are also observed to occur where there is little, or no, water. Studies in the normally frozen Antarctic have shown clear evidence for chemical weathering occurring there. As well as salts such as gypsum and sodium sulfate formed by recrystallization from elements leached from rocks by occasional (liquid) water, abundant iron oxides also occur (Claridge, 1965). Furthermore, clay minerals occur—most commonly transformation products of micas such as vermiculites, but also montmorillonite. This last mineral was thought to form in the arid and highly alkaline environment by similar processes to

those seen in other terrestrial environments, but occurring at a much slower rate (Claridge, 1965). Some, but not all, clay minerals in Antarctic soils could be inherited from other land masses to the north (e.g., dust blown from southern South America; Delmonte et al., 2004). Boyer (1975) collected weathering products such as rinds on rocks from part of Antarctica and identified various 2:1 minerals, including chlorite–vermiculite and also identified montmorillonite. These products all indicated that chemical weathering had taken place. In the arid Sahel in west Africa, Ducloux et al. (2002) identified beidellite, kaolinite, and mica in soils. They concluded that these minerals formed by a process called "xerolysis," whereby desiccation in a hot climate leads to protons from dissociated water reacting with crystalline minerals to produce secondary products.

The new frontier for clay mineralogy is outer space, and especially other planets in our solar system, and there has been a particular focus on Mars from a clay mineralogical viewpoint quite recently. Earlier exploration of Mars involved fly-bys, with spectra being used to identify materials on the Martian surface by remote sensing. These data could have been interpreted to indicate the presence of some phyllosilicates (Hamilton et al., 2003), but the evidence was equivocal. The collection of samples by Exploration Rover from the planet's surface showed that the ferric sulfate, jarosite, which is commonly associated with acid sulfate soils on Earth (see Section 20.2.5.3.4), and also possible relicts of gypsum at the Meridian Planum landing site (Madden et al., 2004). Other work on samples from a number of different locations on the planet has confirmed the widespread occurrence of secondary sulfates and also iron oxides (Hurowitz and McLennan, 2007). Hurowitz and McLennan (2007) considered that they originated from altered olivines in Martian rocks. These various localized occurrences of sulfates and iron oxides were compared with the results of a general survey of most of the surface of Mars that was carried out by an image spectrometer during an aerial survey of the planet (Poulet et al., 2005). The survey had earlier identified sulfates in localities in addition to those reported by Madden et al. (2004) and Hurowitz and McLennan (2007), but Poulet et al. (2005) also identified phyllosilicates in several localities, albeit that their distribution was quite heterogeneous. They included Fe/Mg smectites in some areas and montmorillonite in others. These occurrences suggested that there had been water in some localities on Mars, in order to alter basaltic and similar rocks to give phyllosilicates, although the sulfates derive from a different, more acidic, environment. More recent work (e.g., Bishop et al., 2008; Mustard et al., 2008; Ehlmann et al., 2009) has identified phyllosilicates in a number of localities on the surface of Mars. The discovery of phyllosilicates has aided our understanding of the climatic history of Mars (Newsom, 2005; Poulet et al., 2005). On Earth, meteorites considered to have come from Mars have been studied for their mineralogy, and iddingsite, comprising a mixture of smectites, iron oxides, and silica, has been identified on the altered surfaces and in the veins of the meteorites (Wentworth et al., 2005). These authors drew an analogy between mineral alteration and formation that has taken place on Mars with that which has occurred—and is

occurring—in the Dry Valleys of Antarctica. Examined at the submicroscopic scale, the patterns of alteration of primary silicates, for example, amphiboles and pyroxenes, were similar in an Antarctic Dry Valley (Wright Valley) and in the Mars meteorites (Wentworth et al., 2005). In addition, soils in the Dry Valleys contain evaporated salts at their surfaces, as have been seen in soils on Mars. In both of these arid situations, alteration processes and their products are distributed heterogeneously, indicating an uneven distribution of water available for the alteration and subsequent formation of minerals, both in space (in the Antarctic Dry Valleys) and in time (in the Martian past).

20.2.5.3 Biota as Important Agents in Mineral Alteration and Formation

It has long been recognized, including by the pioneers in pedology, for example, V.V. Dokuchaev and Hans Jenny, that biota play an important, sometimes dominant, role as one of the agents in the development of soils from rocks and other geological materials. Plants, animals, and microbes share an equivalent status to parent materials, climate, topography, and time as soil-forming factors. Therefore, it comes as no surprise to find that biota in their different forms demonstrably play a major role in the alteration of primary minerals and the formation of secondary clay minerals.

Even so, it is arguable that the role of biota in the formation of clay minerals has been relatively neglected in comparison with those of other soil-forming factors, such as parent materials and climate. Churchman (2000) noted that studies of the alteration and formation of minerals had largely concentrated on processes involving inorganic agents, while observing that there had been an upsurge in studies of the role played by biological and biochemical agents in the previous decade. The effect of these agents on weathering changes is now one of the more active areas of research on mineral alteration and formation in relation to soils (e.g., Dong et al., 2009).

20.2.5.3.1 Plants as Weathering Agents

Plants have been shown to be important weathering agents. Mortland et al. (1956), Hinsinger et al. (1992, 1993), and Hinsinger and Jaillard (1993) showed that trioctahedral micas in soils lost potassium from their interlayers as a result of the growth of plants in the soils. In general, this process is that of vermiculitization (or the formation of beidellitic smectites) (Section 20.2.4.3). However, it generally occurs via mixed-layer randomly interstratified species. In soils, illite–smectites are the most common form of these (Velde and Meunier, 2008). Indeed, since this type of clay mineral is not found in buried sediments or rocks, it is peculiar to the soil environment, according to these authors. Furthermore, it is found particularly in the A and B horizons of soils (the solum), confirming its origin in surface alteration processes (ibid.). Although plants, in general, are the main agents of alteration of trioctahedral micas to produce illite–smectites, Velde and Meunier (2008) summarized observations in the literature to conclude that prairie soils (Mollisols) dominated by grasses contain illite–smectite together with varying amounts of illite under different climate conditions. Even

though vermiculites are rare in prairie soils, they can occur in significant amounts in young mountain soils according to Velde and Meunier (2008). Expanded (to vermiculite or smectite) and partially expanded (to mixed-layer illite–smectite) products occur, and these often acquire Al-hydroxy interlayers (see Section 20.2.4.3) under forest (Velde and Meunier, 2008). It was the development of a method of XRD peak decomposition by Lanson (1997) that enabled the detection of some of these mineral changes attributable to plants, which can be subtle.

Acidification can be an important effect of plant growth and consequently can play an important role in alteration by weathering. Protons are released into soil solutions to balance the overall charge when roots take up more cations than anions (e.g., Hinsinger et al., 2001; Courchesne, 2006; Calvaruso et al., 2009). For some tree species, it is the uptake of NH_4^+ in preference to NO_3^- by roots that ensures acidification, specifically in the rhizosphere (Calvaruso et al., 2009). Roots (and fungal hyphae tips as noted above) also exude organic acids into soils (Courchesne, 2006). More Ca, Na, Mg, Si, and especially Fe were released from leached basalt when plants were grown in the fresh rock than when there were no plants (Hinsinger et al., 2001). When soils within the rhizosphere of a Norway spruce and an oak were compared with the bulk soil, it was found that Fe and Al, and therefore their "amorphous" (i.e., nanocrystalline) mineral phases, as well as Al-hydroxy interlayers in 2:1 Si:Al aluminosilicates, were dissolved as a result of acidification by the plant roots (Calvaruso et al., 2009). Forest soils in Taiwan showed a lack of hydroxyl interlayering of 2:1 Si:Al aluminosilicates in the surface O, A, and E horizons but there was interlayering, which was shown to involve both Al and Fe, in deeper horizons (Pai et al., 2004). It was thought that a low pH and possible chelation of Al and Fe by organic material, which was abundant in and on the surfaces of the soils, led to the clean interlayers in the expandable aluminosilicates near the surface, whereas the higher pH and lower organic contents in lower horizons were conducive to their formation in the clay minerals there (Pai et al., 2004). In a later study, Pai et al. (2007) found that acidification at the surface of forest soils elsewhere in Taiwan decreased the charge of the K-depleted aluminosilicate layers, which they characterized as vermiculite, occurring either as the discrete phase or in mixed-layers with vermiculite. In the North Island of New Zealand, Jongkind and Buurman (2006) found that weathering under kauri (*Agathis australis*) trees, which produce especially low pHs (4.0 ± 0.2) left vermiculites depleted of hydroxyl interlayering and even brought about some conversion of vermiculite to smectite, as Churchman (1980) had found to occur in soils under another native (beech) tree species (*Nothofagus* sp.) in the South Island of New Zealand. By matching the rare-earth compositions of the silica particles found within the roots of ferns with those of aluminosilicate minerals in the soil surrounding the roots, Fu et al. (2002) found strong evidence for the dissolution of clay minerals to leave deposits of silica following their incorporation into plant roots.

Plants can bring about very rapid changes in soil minerals (Turpault et al., 2008). A seasonal study by these authors showed that in the rhizosphere close to tree roots, mineral dissolution,

with loss of citrate-extractable Al and Si, occurred in surface layers in spring because of enhanced biological activity. That some of the Al came from interlayers was shown in XRD by an increased ease of collapse of these upon K-saturation and also an increase in cation exchange capacity (CEC). There was a corresponding migration of Al and Si to lower layers. Perceptible changes in the XRD patterns occurred within only 3 months.

20.2.5.3.2 *The Special Case of Podzolization*

Organic compounds from the activities and decomposition of biota have long been thought responsible for extracting and transporting Fe and Al ions and incidentally producing new minerals from them in the process of podzolization (e.g., Russell, 1973), even if equally valid inorganic mechanisms have also been put forward for this process (e.g., Farmer et al., 1980; Wang et al., 1986), as will be discussed further.

Podzolization usually involves the intense leaching of parent materials and soils with acidic solutions. In podzolization, Al, Fe, Mg, and Si are mobilized (e.g., Farmer, 1982; Farmer and Fraser, 1982; Farmer et al., 1983; Taylor, 1988; Churchman, 2000; Giesler et al., 2000). Podzolization can be contrasted with the processes, sometimes collectively referred to as "andosolization," involved in forming allophane and other andic soil materials mainly in tephra-derived soils (Section 20.2.4.6). Normally, allophane and other nanocrystalline clays are formed in situ during andosolization (even though the process typically requires desilication via leaching) whereas podzolization always involves the *translocation* of mobile constituents as organic or inorganic complexes, or both, from very acid horizons in the upper profile and subsequent immobilization in lower horizons through an increase in pH, via microbial action, or by adsorption, precipitation, etc. That such movement takes place has been confirmed by micromorphological studies (e.g., Farmer et al., 1980, 1983, 1985; Farmer and Lumsdon, 2001). Broadly speaking, the processes involved in podzolization are as follows: (1) enhanced mineral weathering in upper A and E ("eluvial") horizons; (2) transport of Al, Fe, and Si and probably also organic matter from upper horizons to lower B horizons—either in metal–organic complexes (chelates) or as independent inorganic complexes including "proto-imogolite sols," and as independent organic complexes; and (3) deposition of the Al and Fe as oxides, together usually with allophane, from (according to Farmer et al., 1985) a mixed Al_2O_3–Fe_2O_3–SiO_2–H_2O sol, in so-called illuvial Bs horizons.

There have been a number of theories put forward to explain the changes that take place in soils as a result of podzolization (see Churchman, 2000, for proponents and arguments involved in earlier discussions, and elsewhere in this handbook). Briefly, these can be grouped into two main hypotheses, both of which may apply to some degree depending on site-specific soil environments (e.g., Wang et al., 1986; Lundström et al., 2000): (1) the organic or "fulvate" hypothesis and (2) the inorganic or "proto-imogolite" hypothesis. A third is the so-called rock-eating fungi hypothesis, which is associated with mycorrhizal fungi found in many soils under pines and heaths commonly in parts of Europe and Scandinavia and elsewhere (Jongmans et al., 1997; van Breemen et al., 2000a).

The fungal hyphal tips, which produce organic acids (e.g., citric or oxalic), "drill" directly into mineral grains including feldspars, thereby bypassing the external acid soil solution, and hence the E horizon is regarded as the fungal "eaten" part of the soil.

An eccentric view is that of Do Nascimento et al. (2004, p. 536) who have described podzolization as a deferralitization process whereby the chemical elements that had accumulated during ferralitization are "progressively exported towards the drainage network under the combined effects of waterlogging, organic matter accumulation, and lateral subsurface and surface water flows." In a somewhat related study, Lucas (2001) compared the dynamics operating in podzols with those in ferralsols (Oxisols) regarding the rates of Si recycling (including storage as phytoliths) by plants and the rates of loss, by leaching, of Si and organometallic complexes involving Al, Fe, and organic matter. This author concluded that the main constituents of the "weathering mantle" ultimately depended on the balance between (1) the stability of the clay minerals, sustained by the plant Si cycling, and (2) the leaching of plant-induced organo-Al compounds. These findings were evident in equatorial areas where old soils are markedly affected by biological activity, and they were also seen in temperate areas (Lucas, 2001).

After reviewing the literature, Lundström et al. (2000) concluded that organic complexes were important in both the weathering and deposition (or immobilization) processes and Jansen et al. (2005) also decided, on experimental grounds, that organic matter played an important role in the transport of Al and Fe down profiles to create illuvial horizons, at least in podzols in the Netherlands and similar climatic zones, while conceding that podzols may form by slightly different mechanisms in both cooler and warmer climatic zones. Contrary views are evident in, for example, Farmer and Lumsdon (2001) who argued that "fulvic acid plays no active role in podzolization, but only recycles Al and Fe, that has been transferred by biological processes to the O horizon, back to the Bh horizon" (p. 177). Buurman and Jongmans (2005) proposed that podzolization in boreal zones, on nutrient-rich parent materials at high latitudes and high altitudes, hence cold climates, occurred with organic matter (OM) dynamics that led to little accumulation of OM (so-called "fast" OM dynamics), and, hence, illuvial B horizons were dominantly inorganic. These authors proposed an alternative route for podzolization in hydromorphic situations on nutrient-poor parent materials, including in warmer climates, where OM dynamics were "slow," by their nomenclature and would lead to organic-rich illuvial horizons.

Regardless of mechanism, podzolization leads to essentially two compartments of the soils according to their weathering status and the nature of the secondary phases (Ugolini et al., 1991). These are (1) the upper horizons, and especially the distinct eluvial (or "fungal eaten") E horizon, and (2) the taxonomically diagnostic lower illuvial horizons, and especially the equally distinct Bh and Bs horizons. (Both or only one of the Bh or Bs may be present in podzol soils.) Considerable recent effort has been expended into studying the early stages of podzolization, largely in soils in the boreal zone, namely, under forests, in northern and/or alpine Europe, from a mineralogical viewpoint

(Melkerud et al., 2000; Mossin et al., 2002; Mokma et al., 2004). Mokma et al. (2004), tracing the earliest stages of podzolization in sandy soils in Finland, found visual evidence for translocation of C, Al, and Fe after 230 years of soil formation while there was evidence of allophane in a Bs horizon after 900 years. There were few differences between the crystalline minerals in the soils of different ages (up to 11,300 years). Buried podzol profiles in northern New Zealand exhibit thin E, Bh, and Bs horizons (about 20, 2, and 5 cm in thickness, respectively) formed on a pumiceous rhyolitic tephra layer deposited in ca. AD 232. The Bs horizons contain allophane. The developing podzols were subsequently buried in ca. AD 1314 by deposition of another rhyolitic tephra (Lowe, 2008). The profiles thus reflect about 1082 years of podzolization under ~1500 mm annual rainfall in a mesic temperature regime under broadleaf–podocarp forest.

In three soils on Quaternary deposits in Fennoscandia, Melkerud et al. (2000) found that the most easily weatherable primary minerals, biotite, chlorite, and hornblende, were depleted from the eluvial horizon, which had the highest concentration of quartz. Vermiculite dominated the clay mineralogy of the E horizons and was also present, but with incorporated Al-hydroxy interlayers, in the B horizon, where poorly ordered or nanocrystalline imogolite-type materials (i.e., allophane) also occurred. Mossin et al. (2002) specifically searched for imogolite in three Danish podzols. Some proto-imogolite allophane rather than imogolite per se was found, but in smaller amounts than had been found in podzols further north in Scandinavia and not at all under spruce, which was responsible for the lowest pH for the soils. They ascribed the generally relatively lower contents of allophane to a lower pH, an increase in organic matter, and a parent material with a low content of easily weatherable minerals. The pH conditions and other factors such as aluminum extractability and solubility are important in explaining the differences in composition in different parts of the podzol profile (e.g., Zysset et al., 1999; Lundström et al., 2000; Farmer and Lumsdon, 2001).

Recently, several other authors have particularly examined the effect that the podzolization, namely, acid leaching, process has had upon micaceous clay minerals. The results of some earlier studies of this kind are discussed in Section 20.2.4.3 and also earlier in this section herein and in Churchman (2000). While the general consensus from earlier studies was that beidellitic smectites are often identified as a stable phase, if not an end product, of the alterations of micaceous minerals that take place in podzol E horizons as a result of eluviation, Righi et al. (1999), Gillot et al. (2001), Mirabella and Egli (2003), and also Egli et al. (2004) have all found that the smectites that form in this way can be quite complex. They constitute a mixture of several populations with various layer charges (Gillot et al., 2001). A chronosequence of soils in Finland enabled these last authors to find that the products of mica transformation included both a relatively high-charge ferromagnesian smectite and also a vermiculite with higher charge in younger soils. They thought that the Fe–Mg smectite arose from the transformation of the ferromagnesian primary mineral biotite and from Fe–Mg-bearing chlorite present in the rocks, whereas the vermiculite, which was aluminous, was a transformation

product of dioctahedral micas (muscovite and phengite). In older soils, smectites with a lower charge resulted from both the dissolution of the higher charged trioctahedral smectites and also a progressive decrease in the charge of the dioctahedral expanded phases (Gillot et al., 2001). Righi et al. (1999) found the nature of the aluminosilicate products of podzolization in the eluvial A and E horizons differed from those in the B horizons within a different chronosequence of soils. The A and E (eluvial) horizons contained a mixed-layer mica–smectite, and, given time, also discrete smectite from the transformation of dioctahedral mica. The B (illuvial) horizons, by contrast, contained mixed-layered mica–vermiculite and smectite. These last clays were the products of the alteration by transformation of trioctahedral minerals, notably biotite and chlorite (Righi et al., 1999). These authors explained the differences between the transformational products by a difference in the nature of the acids involved as weathering agents in the two different parts (or compartments) of the soil profile. In the upper, eluvial compartment, organic acids are responsible for the mineralogical changes and these are more aggressive than the carbonic acid in the lower compartment, which includes the illuvial horizons (Righi et al., 1999). It is only in the upper compartment that dioctahedral minerals become altered, and the organic acids responsible for the alteration there dissolve the products of weathering of the trioctahedral minerals. Their dissolution leads to phases that are translocated to the illuvial Bh and Bs horizons where they accumulate as "amorphous" (i.e., probably nanocrystalline) Fe and Al oxides and as recrystallized gibbsite in these particular soils (Righi et al., 1999). Studying an altitudinal sequence of five podzolized soils in Italian alpine regions, Mirabella and Egli (2003) also found that the smectites formed in either eluvial or illuvial horizons were highly heterogeneous, mostly comprising mixtures of montmorillonite with interstratified beidellite–montmorillonite, but never consisting of beidellite alone. Some were interlayered with hydroxy-Al species, which needed to be removed by citrate treatment before the underlying phases could be distinguished, but their removal showed that the specific expandable micaceous phases with their variety of layer charges had been formed prior to interlayering (Mirabella and Egli, 2003). The most intense weathering, leading to the lowest charged smectites, occurred in podzols below the tree line but closest to it. Clearly, in many of these studies, certain trees are a major factor in the intensification of the podzolization process, if not in its occurrence, in some environments. Churchman (1980) also found that, although podzolization could occur under grasslands provided the rainfall was sufficiently high, the mineralogical changes to micaceous phases were more advanced in soils that were just a few meters away, but which were below the tree line. In the podzols under grassland on both mica–chlorite schist and graywacke lithologies, regularly interstratified mica–beidellite dominated the clay fractions and there was no discrete beidellite present, but discrete beidellite occurred in substantial amounts in podzols under native *Nothofagus* beech forest in New Zealand (Churchman, 1980).

Although beidellitic smectites appear to constitute a stable phase in podzols formed in boreal zones, there can be a sequence

of products formed at different stages during the podzolization process, as discussed by, for example, Churchman (2000), and also by Righi et al. (1999). Studying seven podzol profiles in the Tatra Mountains in Poland, Skiba (2007) has concentrated on the alteration processes of dioctahedral micas within all parts of these soils. This author found a variety of transformational products of dioctahedral micas that varied in the regularity of ordering of their interstratifications with (at first) vermiculites, in the expandability of the vermiculites formed, both as interstratified layers and also as discrete phases, and in the degree of interlayering of vermiculites with smectite, leading ultimately to a discrete smectite phase. Many of these also exhibited interlayering with hydroxy-Al species when pH was ≥4.4. Skiba (2007) also claimed that kaolinite formed neogenetically in these podzols from Al and Si released by weathering.

Three podzols forming in tropical and subtropical climatic zones have been studied in Taiwan by Lin et al. (2002), among others. There was a very similar mineralogical pattern to those seen in podzols in the cooler boreal zone. Illite was altered to vermiculite, or sometimes to interstratified illite–vermiculite in eluvial horizons. There was no interlayering with hydroxy-Al species in the eluvial horizons, which exhibited very low pHs under forest but some occurred in B horizons at higher pHs, and Lin et al. (2002) also considered that translocated Fe, Al, and organic acids coated the Al-interlayered vermiculitic phases with organometallic compounds and thus stabilized them against breakdown. As in many other podzols, the system was characterized by the eluviation, translocation, and deposition of mainly Al and Fe by organic acids.

The general mineralogical pattern in podzols is summarized in Box 20.4. It is given for podzols on micaceous parent materials, which are common for many podzolized soils, although podzols can form on many parent materials or lithologies.

20.2.5.3.3 *Apparent Counteraction of Weathering by Plants*

Some work has indicated that plants, as well as acting as potential weathering agents, may also act to counter the course of mineral development that might otherwise be expected from the operation of the other main weathering agents such as climate. Thus, in a chronosequence on basalt in the tropics, both the early formation of an illite and also a lower content of gibbsite in A horizons than in C horizons across much of the sequence were attributed by He et al. (2008) to the transport by plants of nutrients (K, and also Si, as siliceous phytoliths) to the surface of soils. Together the increases in these nutrients have led to the formation and retention of illite and 2:1 aluminosilicates more generally, at least until they are finally weathered out in the oldest soils. Both April and Keller (1990) and also Calvaruso et al. (2009) found that there was a buildup of the discrete mica phase (respectively muscovite and illite in the two reports) relative to its degraded counterpart in the rhizospheres of trees in comparison with the bulk soils. Barré et al. (2009) have concluded from a review of the literature that this effect of plants retarding weathering changes, which is known as "nutrient uplift," "element translocation," or "biological pumping," is widespread, and that "the clay mineralogy observed in surface soils is probably largely plant mediated." The uptake and biocycling of Si by plants has also been studied by Drees et al. (1989), Lucas et al. (1993), Derry et al. (2005), Farmer (2005), and Henriet et al. (2008). The concentration of Si by "nutrient uplift" has probably contributed, at least, to the preservation of kaolinite and halloysite, respectively, in the surfaces of forest soils in Brazil (Furian et al., 2002) and Costa Rica (Kleber et al., 2007), while strong tropical weathering has led to gibbsite dominating the mineralogy of the saprolite in the Brazilian case and the subsoil in the Costa Rican one. An examination of published data on Si concentrations in Bs horizons in several European forest soils, as well as experimental data for some of these, led Farmer et al. (2005) to postulate that plant phytoliths provide a sink, hence short-term nutrient uplift, for Si from soil solutions during the growing season that is released back to solutions during winter and spring. Such a viewpoint is supported by data derived from studies of plant-related movement in soils of Al and Fe as well as that of Si in both temperate and tropical soils that were reviewed by Lucas (2001), although differences are evident for different environments (see Figure 6 in Lucas, 2001). Nonetheless, Lucas (2001) concluded

---

Box 20.4   Mineralogical Pattern in Podzols Developed on Micaceous Parent Materials

	Horizons	Type	Alteration	Phyllosilicates	Nanocrystalline (SRO) Minerals
Incr. Al, Fe, pH ↓	A, E	Eluvial	Accelerated loss of cations including Al, Fe, K, Si	Beidellitic or smectite or vermiculite; interstratified with illite, or discrete	—
	Bs, Bh	Illuvial	Normal extent of alteration, for example, for climate	Vermiculitic, *not* smectitic, i/strat. or discrete, poss. Al-interlayered	Allophane and/or imogolite, Fe oxides, especially ferrihydrite

that in most places (tropical as well as temperate), the weathering mantle can be regarded as being in a "dynamic equilibrium sustained by plants." Derry et al. (2005) found that most of the silica released to Hawaiian stream water had passed through the biogenic silica pool rather than originating directly from mineral–water reactions in soils in this basaltic environment.

20.2.5.3.4 Humans and Other Fauna as Weathering Agents

The human being is one biological agent with a potential to affect soil mineralogy, which cannot always be ignored. Apart from such effects on soil mineralogy as those from enhanced erosion—leading to, for example, truncation of profiles and transportation of soil minerals over distances from a few meters to the diameter of an entire hemisphere (e.g., Syers et al., 1969) by water or wind—people's activities can also either enhance or retard the influence of other organisms on mineral weathering, whether through the effects of agriculture, pollution, construction, and engineering activities and/or effects on climate and hydrology at either local or global scales (e.g., see Yaron et al., 2010). In the particular case of acid sulfate soils, which are increasing in area globally because of human activities, and which are of increasing concern as a form of both soil and environmental degradation (Dent and Pons, 1995; Ritsema et al., 2000), large-scale changes wrought by humans have led to mineralogical changes, which contribute to the properties of these soils, which have been labeled "the nastiest soils in the world" by Dent and Pons (1995). Classed often as Sulfaquents, acid sulfate soils, which are most commonly coastal, but may also occur in nontidal seepage and marsh areas affected by dryland salinity (Fitzpatrick et al., 1996), originate from the oxidation of sulfides, most commonly of Fe and most often pyrite FeS_2, but sometimes also Fe monosulfides such as mackinawite (tetragonal FeS), pyrrhotite (hexagonal FeS), and greigite (Fe_3S_4) (Burton et al., 2009). These Fe sulfides are themselves products of earlier bacteria-mediated reduction of sulfate ions (Dent and Pons, 1995; Fitzpatrick et al., 1996). Sulfuric acid results from the oxidation of the sulfides (such as occurs after draining the soils), which occurs only slowly in an abiotic environment, but which is greatly accelerated in the presence of Fe-oxidizing bacteria (Ritsema et al., 2000). The sulfuric acid thus produced reacts with soil minerals generally to give a range of compounds. Of these, jarosite ($KFe_3(OH)_6(SO_4)$), also known as "cat clay" because of its yellow, fecal-like color, is most widely recognized as a component of acid sulfate soils (Dent and Pons, 1995; Fitzpatrick et al., 1996), and schwertmannite ($Fe_8O_8(OH)_{8-2x}(SO_4)_x$), has been recognized in some under very acid conditions (Fitzpatrick et al., 1996; Burton et al., 2006, 2008). The Fe oxidic phases, ferrihydrite $Fe_5HO_8 \cdot 4H_2O$ and goethite, can also form (op. cit.), but many other minerals have been found to form as a result of the processes contributing to the evolution of these soils. These minerals include hydrated sulfates of Na and Fe (sideronatrile and natrojarosite), Na and Al (tamarugite), Mg and Fe (copiapite), and Pb and Fe (plumbojarosite), as well as gypsum, halite, the Fe oxyhydroxide, akaganéite, and a poorly ordered Al oxyhydroxide (R.W. Fitzpatrick and M.S. Skwarnecki, unpublished results), as well as elemental sulfur (Burton et al., 2009). In the case of acid

sulfate soils, the effects of human intervention in certain environments have been to promote mineralogical changes that are mediated by microbes.

Agriculture brings about disequilibrium in soils (Velde and Meunier, 2008). The effect of cropping on clay mineralogy was assessed through analyses of samples taken from the long-term Morrow experimental plots at the University of Illinois for >80 years cropping of different types and with different management regimes (Velde and Peck, 2002). Continuous cropping with corn has led to a marked loss of illite in favor of illite–smectite phases. In contrast, rotation cropping over the same period has had little effect on clay mineralogy. However, 80 years of growing rice in flood-irrigated soils in China showed strong effects on clay minerals in the soils (Li et al., 2003). Micaceous phases, including interstratified phases, have largely been lost, as have Fe oxides, but a Si-poor ferromagnesian chlorite has formed. Pastures can also influence clay mineralogical development. Poldered sediments in France with up to ~850 years of development under prairie enabled Velde et al. (2003) to show that the dominantly illite–smectite clay minerals in topsoils, which were influenced the most by grass growth, hardly changed with time from those in the sediment. On the other hand, the same type of clay minerals in the subsoils became more smectitic over the same time period. The subsoils had a higher pH than the topsoils, which were more-or-less neutral in pH. The grasses appeared to stabilize the particular mixed-layer composition of the original clay minerals.

The common agricultural practice of adding fertilizers to soils can also have effects on the mineralogy of soils. Thus, Simonsson et al. (2009) found that soils subjected to the long-term use of K fertilizers had contents of illite, both as a discrete phase and also within mixed layers, which reflected the rate of addition of the fertilizers—illite was more concentrated where fertilizer additions had been higher. K release from the soil minerals appeared to be reversible except where hydroxyaluminum interlayers occurred, presumably blocking K^+ from entering or leaving the interlayers (Simonsson et al., 2009). Velde and Peck (2002) also found that additions of NPK fertilizer after >40 years of continuous cropping with corn restored the clay minerals to their original state whereas, as already noted, illite was sufficiently depleted of K over >80 years of this treatment without fertilizer additions to register a significant change to illite–smectite (I–S). These authors suggested that I–S plays the role of a K buffer that releases K when plants cannot access other sources of this essential nutrient and stores it when there is an excess of K. Pernes-Debuyser et al. (2003) found that the content of nonexpandable illite increased at the expense of expandable I–S in long-term K-addition treatments of soil without plants with either KCl or manure at Versailles in France. Fertilization with ammonium-based N-fertilizers has also been shown to affect clay mineralogy through an increase in the contents of nanocrystalline aluminosilicates and also hydroxyl-Al interlayers in 2:1 minerals (McGahan et al., 2003). On the contrary, Tye et al. (2009) noticed that the greatest mineralogical changes in the long-term plots at Rothamsted in the United Kingdom occurred when fertilization with ammonium sulfate led to pHs falling below 3.7, when

hydroxyl-Al interlayers in 2:1 minerals became solubilized, allowing entry of the interlayers to K^+ and NH_4^+.

Fauna can also aid weathering processes by moving soil materials, especially by bringing less-weathered or unweathered subsurface materials to the soil and land surface as occurs by termites for example in building mounds, and worm ingestion and excretion (e.g., Paton et al., 1995; Johnson, 2002; Meysman et al., 2006). In maritime Antarctica, which receives more liquid water than the Antarctic continent, ornithogenic soils formed on basaltic and andesite rocks in abandoned penguin rookeries and which are organic-rich due to penguin guano show considerable development of secondary minerals, mainly as noncrystalline or nanocrystalline phases, including 1:1 (Al:Si) allophane (Simas et al., 2006).

20.2.5.3.5 Microorganisms as Weathering Agents

It is well recognized that microbes act as reducing agents and thereby contribute to the reassignment of Fe and Mn from primary minerals or secondary oxides, oxyhydroxides, and hydroxides into solution and ultimately into new oxidic phases upon drying, sometimes with the solubilization and release of trace metals such as Co and Ni (e.g., Quantin et al., 2001). Microbes also act commonly as oxidizing agents (such as in the formation of ferrihydrite in seepages). Their activity, when simulated by a series of oxidation-reduction cycles, transformed the short-range-ordered iron oxide "nanogoethite" to microcrystalline goethite and microcrystalline hematite (Thompson et al., 2006). They may also bring about mineral alteration through root exudates, as in the tunneling action of fungal hyphae on feldspars and other mineral grains (van Breemen et al., 2000b; Smits et al., 2005, see Section 20.2.4.2). Müller (2009) has shown that the weathering effect of bacteria can vary greatly between different genetic derivatives of a single strain. Organic acids resulting from the life and death of organisms have also been recognized as important agents in mineral alteration (e.g., Huang and Schnitzer, 1986; Robert and Chenu, 1992). In particular, dicarboxylic acids have been identified in soils (Hue et al., 1986) where they greatly enhance rates of dissolution (Amrhein and Suarez, 1988) through ring compounds as ligands for sequestering metals on mineral surfaces (Casey, 1995). One of the main effects of organic acids on weathering may come through their supply of protons (Ugolini and Sletten, 1991; Nesbitt, 1997). It has also been shown in nature and in experiments that both aluminosilicate minerals and oxides of Fe and Mn can form by nucleation on bacteria (Urrutia and Beveridge, 1994; Ferris, 1997; Tazaki, 1997, 2005; Chan et al., 2009). Magnetite formed partly by bacteria in soils has been described, for example, by Maher and Taylor (1988) and Geiss and Zanner (2006). Observations made by Ueshima and Tazaki (2001) in both deep-sea sediments and laboratory experiments showed that aluminosilicates (nontronite in this case) could be formed on extracellular polysaccharides from microbes. The role of microorganisms in the weathering of glass or volcanic materials has been described, amongst others, by Thorseth et al. (1995), Kawano and Tomita (2001, 2002), and Stroncik and Schmincke (2002). According to the last authors,

bacteria and microorganisms create a local microenvironment as a result of the fluids of their metabolic products. These fluids are either acidic or basic in pH, depending on the type of bacteria: an acidic pH essentially results in incongruent glass dissolution, whereas a basic pH results in congruent glass dissolution, leaving large pits on the glass surface (Stroncik and Schmincke, 2002). Microbial activity thus enhances the rate of dissolution of volcanic glass and microbial alteration also results in the formation of authigenic phases and is accompanied by redistribution of elements.

Hence, microorganisms may play a number of roles in mineral weathering. As summarized by Barker et al. (1997), these include the following: (1) physical disintegration of rocks; (2) production of acids and chelating ligands to accelerate chemical alteration; (3) stabilization of soils to increase their time of exposure to chemical agents; (4) production of extracellular polymers to moderate water potential, maintain diffusion channels, and themselves act as ligands for chelation and also as nuclei for mineral neoformation; and (5) absorption of nutrients to lower solution concentrations and increase the chemical potential for weathering. All these roles may also be performed by plants, including grasses, crops, and trees (e.g., Courchesne, 2006). In addition, they may be carried out by other biological agents, including lichens (Adamo and Violante, 2000; Chen et al., 2000), fungus-growing termites (Jouquet et al., 2002), and mycorrhizal fungae (Jongmans et al., 1997; van Breemen et al., 2000a, 2000b; Certini et al., 2003). With regard to mycorrhizal fungae, the cited authors concluded that the fungal hyphae dissolved and extracted nutrients directly from mineral grains, such as feldspar and hornblende, through their intrusion into fractures and fissures in the geological deposits and by "drilling" directly into minerals, thereby bypassing the external solution phase. However, in studying the microbiological colonization of primary mineral weathering in volcanic soils in Italy, Wilson et al. (2008) found in this case that microbial activity, particularly fungal activity, was not an effective agent of mineral weathering, that the association with clay minerals was indirect, and that fungal weathering of primary minerals was probably less important than previously claimed as a source of plant nutrients. These authors concluded that preformed cleavages and microporous features in primary minerals enable the penetration of fungi for them to bring about mineral alterations and noted that these features were generally absent in the soils they studied.

20.2.5.3.6 The Ecology of Biota and Soil Minerals

Bennett et al. (2001), in noting that microbes bring about the alteration of minerals through their selective extraction of essential nutrients from the minerals, posed the question of whether the suite of microorganisms is partly, at least, controlled by the mineralogy and by the ability of particular microorganisms to use the nutrients contained within the minerals present. Soil minerals, both primary and secondary, may thus be viewed in the ecological context that is characterized by Young and Crawford (2004) as "the soil-microbe complex." Building on the concept of plants as ecosystem engineers, and on published information on

the effects of particular plant species on soils, van Breemen and Finzi (1998) reviewed the evidence that such effects can provide a positive feedback to such plants. They concluded that there was strong evidence for plant-soil feedbacks in a variety of ecosystems, and they argued that these feedbacks could have played a role in the evolution of the plant species in question. Earlier, van Breeman (1992) had asked the question: "have soils merely been influenced by biota or have biota created soils as natural bodies with properties favorable for terrestrial life?" Coleman and Crossley (2003) argued for the latter by reference to the storage in soils of the life-limiting element, phosphorus. They contended that (1) the interaction of biota with primary minerals produces soluble Fe (and other cations) by weathering; (2) Fe in particular is brought into the solid phase as oxides (including oxyhydroxides) by oxidation aided by (iron oxidizing) bacteria; and (3) the Fe oxides are kept in a largely amorphous or nanocrystalline form, from which P can be extracted by plants more efficiently than from crystalline oxides, through their interaction with (biota-derived) humic substances. Recent experimental

work has shown both that (1) bacteria can effect the production of polymeric molecules within the structures of (smectitic) clay minerals, hence probably improving the environment for the survival of the bacteria (Alimova et al., 2009), and (2) the structure of bacterial communities in soil is influenced by the (primary) minerals in their microhabitat (Carson et al., 2009). Chickens and eggs come to mind in assessing whether biota or minerals are the limiting factors in the ecology of the soil, but it is clear that, while both are important, it is their interactions that are of overriding and vital importance to the sustainable functioning of soil and the life it supports.

20.2.6 Processes of Mineral Alteration and Formation by Weathering: Summary

Secondary minerals are formed as a result of the alteration of primary minerals or mineraloids by either (1) transformation in the solid state or (2) hydrolysis, dissolution, and recrystallization out of solution, namely, neogenesis. Figure 20.9 summarizes these two possible mechanisms.

20.3 Occurrence of Clay Minerals in Soils

This section concentrates on the particular forms in which clay minerals occur within soils, rather than the general groups of soils in which they occur, or even their distribution in particular environments or globally. These aspects are dealt with elsewhere in this handbook. Instead, our focus is on the sizes and shapes of mineral particles and peculiarities of their chemical compositions and crystal structures, largely in relation to those of "type" occurrences of minerals with the same names in more or less pure "geological" deposits, including those often used as standard specimens of each type. In this section, we also explore the associations of minerals within soils in relation both to other types of minerals and also to organic materials. In particular, we examine the possibility that there is a relationship between the mode of formation (and alteration) of clay minerals, on the one hand, and on the other, the forms they adopt and also their associations within soils.

20.3.1 Occurrence of Kaolinite in Soils

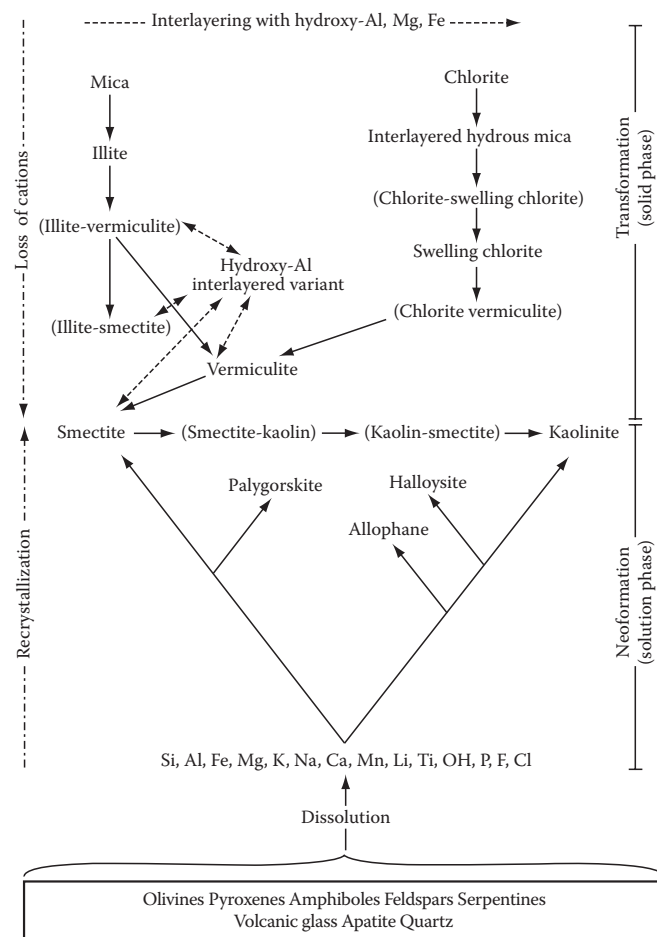
Kaolinite is the most ubiquitous phyllosilicate in soils (White and Dixon, 2002). Nonetheless, kaolinites are most abundant in highly weathered soils, which are formed in warm humid climates, although a high rainfall can result in their formation within soils in temperate climates (Weaver, 1989; White and Dixon, 2002). They can also be found in soils in colder climates that were nevertheless formed under an earlier, warmer climate, for example, by preglacial weathering in Scotland (Wilson et al., 1984). Generally, kaolinites in soils are highly disordered and many of the peaks in their XRD patterns are poorly resolved. As a result, the common index for assessing the degree of crystalline order by XRD, namely, the Hinckley index, is impossible


FIGURE 20.9 Main pathways for mineral alteration and formation in soils via either neoformation (lower part of figure) or transformation (upper part). (After Churchman, G.J. 1978. Studies on a climosequence of soils in tussock grasslands. 21. Mineralogy. N.Z. J. Sci. 21:467–480; Wilson, M.J. 2004. Weathering of the primary rock-forming minerals: Processes, products and rates. Clay Miner. 39:233–266.)

to measure and an alternative, empirical index was devised by Hughes and Brown (1979), which remains in use for soil kaolins (including halloysite). In developing this index, Hughes and Brown (1979) noted that kaolinites in the set of 26 soils they mainly studied, which were from Nigeria, invariably occurred along with other minerals in their clay fractions, as well as containing weatherable minerals in the coarser fractions. These authors suggested that the weatherable minerals present hindered the crystallization of well-ordered kaolins. Millot (1970) had come to a similar conclusion, suggesting more specifically that alkaline-earth cations had caused the inhibition of crystallization. Iron is a common impurity in the kaolinite structure, and there appears to be a relationship between structural Fe and crystalline order (Herbillon et al., 1976; Mestdagh et al., 1980). As Fe increases in amount, displacing the smaller Al atoms from the structure, crystal strain may increase, thereby limiting crystal growth, so that particle size as well as structural order is likely to be diminished by a high Fe content. Lim et al. (1980) had found that nonsoil kaolinites could also be poorly crystallized. Compared with their well-crystallized counterparts, seven examples of these poorly ordered kaolinites, from Georgia in the United States of America, showed not only much higher values for specific surface area particularly (between 78 and 114 m^2 g^{-1}, cf. 10–15 m^2 g^{-1} for the well-crystallized kaolinites), but also some relatively high values for CEC. All were shown to comprise some montmorillonite and vermiculite as impurities, while six of them also contained mica. Kaolinites often occur in vermiform books, suggesting a micaceous precursor. White and Dixon (2002) suggested, rather, that micas, or, more commonly, their expanded transformation products with the same crystal

form, for example, vermiculite or beidellitic smectite, provide nucleation sites on their 001 surfaces for authigenic kaolinite formation, as shown in Figure 20.4.

A number of papers (Singh and Gilkes, 1992a; Melo et al., 2001; Hart et al., 2002; Kanket et al., 2005) have compiled data describing crystal form, measures of crystal order, and related properties such as Fe contents for kaolinites extracted from highly weathered soils in (Western) Australia, Brazil, Thailand, and Indonesia, although the last also included some halloysite or "tubular kaolins" (Churchman and Gilkes, 1989), so the total set is better described as kaolins. Together with information from Hughes and Brown (1979) for Nigerian soils, these properties are able to be compared in Table 20.4 (from Kanket et al., 2005, with data for the reference kaolinites from Hart et al., 2002). The various kaolins had many properties in common. Although there was a range for each value within each set of soil kaolins, their specific surface areas (overall range 34–88 m^2 g^{-1}) all exceeded those of any of the reference samples (all ≤25 m^2 g^{-1}) and their particle sizes, given by coherent scattering domains (CSDs), were generally less than half those of the reference kaolinites. Surface areas and particle sizes are expected to be inversely related to each other. Their Hughes and Brown (HB) index values were always less than those of the reference kaolinites, and, although some of the soil kaolins had quite high CECs, some were comparable to those of several, at least, of the reference kaolinites. Regardless of their other characteristics, however, all of the soil kaolins on which Fe was measured (those from Thailand, Western Australia, and Indonesia) had much higher contents of Fe than the reference kaolinites. With the most clear-cut differences between soils and reference kaolinites being in their surface areas, the HB measure

FIGURE 20.10 Transmission electron micrographs showing comparisons between some soil kaolinites from Western Australia and a reference kaolinite (from Georgia). Eh indicates a euhedral hexagonal shape for particles in the reference sample. (Micrographs copied from Singh, B., and R.J. Gilkes. 1992a. Properties of soil kaolinites from south-western Australia. J. Soil Sci. 43:645–667. Reproduced with permission of Wiley-Blackwell.)

of structural order, and their Fe contents, these results bear out the proposition from Herbillon et al. (1976) and Mestdagh et al. (1980) that a high Fe content leads to a low degree of structural order and small particles. Their small size, particularly, is illustrated by transmission electron micrographs showing comparisons between some soil kaolinites from Western Australia from Singh and Gilkes (1992a) and a reference kaolinite (from Georgia) (Figure 20.10). Furthermore, Singh and Gilkes (1992a) found that the kaolinites contained both K and Mg, which are largely absent from pure, well-crystallized kaolinites. Brazilian soil kaolinites were also found to contain considerable K and Mg (Melo et al., 2001). These authors suggested that there are residual micaceous layers incorporated in the kaolinites. This finding is consistent with the results of Lim et al. (1980) and also with the common observation that kaolinites appear in vermicular books by crystallization on the surfaces of micas and their transformation products (Figure 20.4). The crystal growth of the kaolinites may have been constrained by interleaved micaceous layers as well as by Fe incorporated into the kaolinite layers.

Kaolinite (and also, we shall see, halloysite) quite often occur in interstratifications with a smectite. Kaolinite–smectite interstratified phases have been found to occur worldwide, including in Scotland, Canada, throughout Africa, Australia, Central America, India, Japan, China, and the United States (see Churchman, 2000, for citations), and a more recent report (Vingiani et al., 2004) described their occurrence in Italy (Sardinia). Norrish and Pickering (1983) speculated that

kaolin–smectite interstratified phases (or "kaolin–smectites") are likely to be a very common component of Australian soils. In Australia, and elsewhere, they have probably been often overlooked in identifications using XRD patterns. This "omission" is because the main effect of the mixed layering is to broaden and weaken XRD peaks, so that basal peaks may become invisible even though nonbasal peaks appear (Norrish and Pickering, 1983). In part, this effect is a consequence of the inherent variability of clay minerals in soils, so that the properties of the two (and sometimes more) components and their degree of order can vary from particle to particle (ibid.). Most kaolinite–smectites described in the literature are more kaolinitic than smectitic (Churchman et al., 1994), although Bühmann and Grubb (1991), Churchman et al. (1994), and also Ryan and Huertas (2009) each found examples where the proportion of smectite layers was >60%. In the same way that many interstratified specimens with high concentrations of kaolinite have been identified incorrectly as kaolinites (Norrish and Pickering, 1983; Churchman et al., 1994), so also some with high contents of smectite have been misidentified as smectites (Cuadros et al., 1994). Some with a high kaolinite content were probably misidentified as halloysites that have a platy morphology (Carson and Kunze, 1970; Wada et al., 1987), but each of these was later interpreted as a kaolin–smectite by Sakharov and Drits (1973) and Parfitt and Churchman (1988), respectively. The identification of phases as kaolin–smectites rather than as either of their components is important in order to fully describe the effect of clay mineralogy on soil properties

such as CEC (e.g., Seybold et al., 2005) because they give rise to higher values than can be expected from kaolinites and lower values than from smectites.

Kaolinite–smectites have been found in intermediate zones in toposequences spanning smectitic black soils at their base and kaolinitic red soils near their summits and on their steep slopes (Herbillon et al., 1981; Bühmann and Grubb, 1991; Delvaux and Herbillon, 1995; Vingiani et al., 2004). They have also been recognized within single soil profiles on basalt (Churchman et al., 1994; Vingiani et al., 2004). From the base of the profile to near its surface, their composition changed from highly smectitic to highly kaolinitic, but nonetheless with both phases being interstratified kaolinite–smectites (Churchman et al., 1994), or else more subtly, from ~35% to 40% to ~40% to 45% kaolinitic within the interstratifications (Vingiani et al., 2004). Ryan and Huertas (2009) have also located kaolinite–smectites in a set of soils within a chronosequence on mostly basaltic and andesitic parent materials. As it was within the residual soil profiles on rock (Churchman et al., 1994; Vingiani et al., 2004), the progression from youngest (found at the base of the profiles) to the oldest (at the surface in the case of the profiles) was from more smectitic (or pure smectite, in the chronosequence) to more kaolinitic. Kaolinite also occurred as a discrete phase alongside its interstratifications with smectite in the most developed (i.e., oldest) soil in the chronosequence of Ryan and Huertas (2009) and also in the soil profiles of Churchman et al. (1994) and Vingiani et al. (2004). A variety of techniques, including XRD, together with modeling of the effect of interstratifications and sometimes also peak decomposition, FTIR, HRTEM, differential thermal analysis (DTA), and permanent and variable charge analysis, have enabled various authors to seek an understanding of the origin of the process of interstratification of the 2:1 and 1:1 layers. Ryan and Huertas (2009) concluded that a layer-by-layer transformation occurs as smectite is progressively altered to kaolinite via an interstratification of the two endmember phases with each other. The transformation proceeds by localized dissolution of the 2:1 layers with initial loss of Fe and Mg from octahedral sheets and of Al from tetrahedral sheets followed by a loss of Si from tetrahedral sheets ("subtraction") and/or a deposition of hydroxyl-Al species in interlayers, leaving 1:1 layers ("addition") (Ryan and Huertas, 2009). These two alternative types of mechanism for the alteration had been proposed earlier by Wada and Kakuto (1983, 1989), who favored a subtraction mechanism, and by Altschuler et al. (1963) and Poncelot and Brindley (1967), who favored an addition mechanism. Albeit through studying a clay deposit rather than a soil, Watanabe et al. (1992) found support for a subtraction mechanism as a result of their discovery that opal C–T, or microcrystalline opal comprising clusters of stacking of cristobalite and tridymite over very short length scales, forms during the early stages of formation of kaolinite from smectite. Vingiani et al. (2004) discovered that the smectite in the sequence they studied consisted of a mixture of a more ferric and a more aluminous type. In the course of mineralogical evolution, there was a decrease in the proportion of the ferrous smectite layers relative to their aluminous counterparts. These

authors proposed that the (subtraction) mechanism operated through a preferential loss, by either transformation or dissolution of the ferrous smectite layers, to give kaolinite layers, with the excess Fe forming either Fe oxides (or oxyhydroxides) or becoming incorporated in kaolinite layers, or both.

Kaolinites can also form interstratifications with other types of layers besides smectites, for example, vermiculite (Jaynes et al., 1989), and can also participate in interstratified phases involving several different types of layers. The elevated CECs and also high K_2O contents of some of the soil kaolins studied by Singh and Gilkes (1992a), Melo et al. (2001), and Kanket et al. (2005), in particular, are at least partly ascribed to their interstratifications by micas and/or vermiculites. Ma and Eggleton (1999) found that some soil kaolinites in Queensland, Australia, had quite high CECs (16–34 $cmol_+\ kg^{-1}$) and HRTEM had shown that their crystals commonly comprised stacks of many kaolinite layers, which terminated in smectite layers, possibly as single layers. These stack-end smectite layers affected CEC but were usually not detectable by XRD (Ma and Eggleton, 1999).

20.3.2 Occurrence of Halloysite in Soils

As already noted (Section 20.2.4.5), halloysite is a common component of soils formed from volcanic parent materials, particularly tephra including finer components referred to as volcanic ash (e.g., Kirkman, 1981; Lowe, 1986). It has also been identified as a weathering product of a wide range of rock types including nephelinite, granite, gneissic granite and granitic gneiss, gneiss, dolorite, schist, graywacke, greenstone, granodiorite, gabbro, shale, and amphibolites (see Churchman, 2000, and also Joussein et al., 2005, for citations). Halloysite can occur in a variety of particle morphologies including tubes and microtubules, spheroids and microspheres, crumpled lamellae, crinkly films, needle-like or fiber-like forms, and prismatic forms (ibid.; see also Hong and Mi, 2006; Etame et al., 2009). Its morphology appears to relate to the content of impurity iron with substitution of the larger Fe(III) for Al in the octahedral sheet, which, without substitutions, is smaller than the tetrahedral sheet. This situation leads to partial or full correction of the misfit between the octahedral and tetrahedral sheets that, therefore, causes curling (as in tubes) in halloysites with little or no Fe. The impurity Fe also constrains crystal growth and leads to smaller particles being formed. Recently, Singer et al. (2004) have found halloysites with high contents (up to 6.5%) of Ti in their aluminosilicate structure that were plate-like, probably from the same cause: larger Ti atoms replace some Al in the octahedral sheets, hence also correcting at least some of the mismatch with the tetrahedral sheet. Even so, whereas a peculiar shape was once regarded as the distinguishing feature of halloysite in comparison with kaolinite, it is rather the occurrence, or else evidence for prior occurrence, of interlayer water that demarcates halloysites from kaolinites (see Section 20.2.4.6.2 earlier herein). Interlayer water is lost irreversibly from halloysites on drying.

However, some shapes, particularly spheroidal, appear to reflect a particular mode of formation for halloysite (Churchman,

2000). Spheroidal forms of halloysite appear often in weathering products of volcanic glass, which has a fast dissolution rate, and recrystallization from the resulting supersaturated solution appears to favor this particular shape (review by Bailey, 1990; Adamo et al., 2001; Singer et al., 2004), possibly when physically constrained, for example, within pumice cavities (Adamo et al., 2001). Nevertheless, both Churchman and Theng (1984) and Singer et al. (2004) found that spheroidal particles had higher Fe contents than even short tubes, suggesting a structural control on shape for spheroids as well as for tubes. By contrast, Johnson et al. (1990) found a spheroidal halloysite with virtually no Fe whereas Noro (1986) and also Adamo et al. (2001) found few, or only minor, differences in composition between spheroidal and tubular forms of the mineral. In any case, Soma et al. (1992), using XPS, found that Fe content varied between different layers in a halloysite, whether spheroidal or tubular. Furthermore, spheroidal- and tubular-shaped particles occur together in halloysites (Saigusa et al., 1978; Churchman and Theng, 1984), and one may alter to another in situ (Sudo and Yatsumoto, 1977), suggesting there may be no clear-cut distinction between the conditions that lead to the different particle shapes for halloysite. On the other hand, a very detailed microtextural and microanalytical study of samples taken at various depths in a weathering profile on gneiss in Greece led Papoulis et al. (2004) to deduce a sequence of mineral alteration that encompasses different morphologies for halloysite and includes two forms of kaolinite while simultaneously indicating a correlation between structural Fe and the various products in the alteration sequence. Papoulis et al. (2004) divided the alteration sequence into four successive stages. In the earliest stage, halloysite formed in very small spheres (~0.1 to 0.3 μm in diameter) that were located on the surfaces of plagioclase in this case. These small spheres then apparently coalesced to form tubes while new tubes also formed in the second stage. These tubes were generally quite short (<1 μm in length), although they could develop with time to form longer tubes with tapered ends, which, together with a relatively loose packing and subparallel orientation, suggest crystallization from solution (a conclusion supported by studies on halloysite with tapered ends by Hong and Mi, 2006). In the third stage, platy halloysite formed apparently by interconnection of the preformed tubes. This form even occurred in crude booklets, which are commonly regarded as more typical of kaolinites, albeit interleaved with a low proportion of kaolinite plates, according to Papoulis et al. (2004). These authors considered that the platy halloysite was unstable and led to the formation of plates of a poorly ordered kaolinite, with dimensions of ~1 μm in length and ~0.1 to 0.2 μm in thickness. The change from halloysite plates to kaolinite was considered to occur within the single (third) stage by Papoulis et al. (2004). The fourth stage was one of kaolinization, with a disordered kaolinite forming first but with a well-formed book-type kaolinite as the ultimate product. Concomitant with these changes in morphology, increasing Fe in EDAX/EDS analyses of the products through the first three stages led these authors to allocate increasing proportions of Fe in octahedral sheets at the expense of Al, so that spheroidal halloysite had less substitution

of Al by Fe than tubular halloysite, whereas the platy form had the most structural Fe among the halloysites. The poorly ordered kaolinite that developed from halloysite in the third stage had a comparable degree of substitution of octahedral Al by Fe as its supposed platy halloysite precursor, and the disordered kaolinite formed first in the fourth stage had even more substitution of Fe for Al. However, the book-type kaolinite had a vanishingly small content of structural Fe. It was almost pure aluminosilicate. Overall, Papoulis et al. (2004) attributed the changes in the sequence from small spheroidal particles of halloysite through tubular and play halloysite to poorly ordered platy, then well-ordered book-type kaolinite, largely to a changing chemistry of the ambient solutions, with a successively decreasing availability of Fe for incorporation in the aluminosilicate layers, although they conceded some role to microenvironmental conditions (e.g., time, and space available) in affecting particle morphology.

Bailey (1990) concluded that the structural difference between halloysite and kaolinite is substantial enough to make it impossible for one to give rise to the other without dissolution and recrystallization. Nonetheless, there have been many studies showing an apparent genetic relationship between halloysite and kaolinite in weathering profiles including soils and deeper regolith. There is a general trend from halloysite at depth toward kaolinite at the surface of profiles on residual rock materials (e.g., Eswaran and Wong, 1978; Calvert et al., 1980; Churchman and Gilkes, 1989; Churchman, 1990; Takahashi et al., 2001, Singer et al., 2004; Jongkind and Buurman, 2006). These studies together have covered a range of parent rock types and also climates, including tropical (Eswaran and Wong, 1978, and part of Churchman, 1990), temperate (Calvert et al., 1980; part of Churchman, 1990; Jongkind and Buurman, 2006), and Mediterranean, or xeric (Churchman and Gilkes, 1989; Takahashi et al., 2001; Singer et al., 2004). According to Papoulis et al. (2004), these trends with depth were explained in the context of their morphological and compositional development sequence of halloysite and kaolinites. They pointed out that a depth sequence in a residual weathering profile on rock is inter alia also a time sequence, with the earliest stages concentrated at depth and the latest (oldest) stages to be found near the surface (unlike we note the situation in upbuilding profiles where the opposite is true). Like Churchman and Gilkes (1989), these authors considered that the products of the different stages could also exist simultaneously with one another. Singer et al.'s (2004) examination of the weathering of basaltic scoria at a fine scale showed that, whereas 1.0 nm halloysite was found in vesicles in the scoria, where it was protected from dehydration, 0.7 nm halloysite and also kaolinite were found in the less scoriaceous basalt, where minerals had been exposed to seasonal drying. 1.0 nm halloysite was also found in a buried paleosol in the same region. Its burial in the paleosol had protected it from drying. In New Zealand, Lowe (1986) found that 0.7 nm halloysite predominated in the surface horizons of a soil developed on weathered tephra subject to reasonably frequent seasonal drought, whereas 1.0 nm halloysite occurred in deeper horizons that were less affected by drying. An intermediate zone of variably dehydrated

halloysite with XRD peaks between 1.0 and 0.7 nm occurred between upper and lower subsoil horizons.

These findings were corroborated by Churchman et al. (2010), who found that alteration of granite and volcanic tuff in Hong Kong had led to halloysite forming only in veins within the rocks where there was no evidence of drying, namely, no Fe or Mn oxides were present. By the same token, this study showed that kaolinite formed in these veins, either alone or in association with halloysite, where the appearance of Fe and Mn oxides indicated that drying had occurred. A weathering sequence on trachy-basaltic parent materials in Sicily was found to produce imogolite-like allophane (i.e., Al-rich allophane) in the early stages of alteration of volcanic glass and kaolinite, but no halloysite in later stages (Egli et al., 2008). This absence is probably because of the xeric moisture regime in the area. Similarly, basaltic parent materials in a xeric moisture regime in South Australia were found to produce allophane, but not halloysite (Lowe et al., 1996; Lowe and Palmer, 2005; Takesako et al., 2010; also Section 20.2.4.6). Kaolinite per se was not formed in this case, and, although kaolinite–smectite was often present in the soils, it could have been derived ultimately from limestones and calcareous dune sands underlying the basalt that were incorporated into the soil parent material during the basalt emplacement, with 1:1 Al:Si allophane the likely result of further development of initially formed 2:1 Al:Si allophane by resilication. Albeit that a drier regime tends to favor halloysite over allophane in soils from volcanic ash (see Section 20.2.4.6.2), these various observations suggest that the presence of water is a necessary condition for the formation and preservation of halloysite rather than kaolinite under similar conditions of, for example, parent material, temperature, and time.

Even so, a trend from halloysite at depth toward kaolinite at the surface in residual soil profiles does not necessarily imply that halloysite transforms to kaolinite as weathering intensifies with time. Churchman and Gilkes (1989) found rather that hydrated, tubular halloysite, which dominated the clay fraction of the saprolite deep in a lateritic profile in dolerite in Western Australia, became progressively more dehydrated and progressively more difficult to intercalate with the polar liquids—formamide, hydrazine, and a concentrated potassium acetate solution—with closer approach to the surface. As weathering intensified up the profile, kaolinite began to appear as hexagonal particles but by a different pathway from that for halloysite. As has been found elsewhere in the old, strongly leached landscapes of much of Australia (Janik and Keeling, 1993), Churchman and Gilkes (1989) observed that tubular particles with a kaolin layer structure and composition appeared even in the uppermost duricrust of the weathering profile, but they were dehydrated and completely resistant to intercalation by polar liquids.

In seeming contradiction to this trend and also to Bailey's (1990) contention that halloysite and kaolinite cannot transform from one to the other in the solid phase, both Robertson and Eggleton (1991) and also Singh and Gilkes (1992b) showed electron micrographs from within weathering profiles in Australia in which tubular particles, suggesting halloysite, are seen to apparently form on the surface of kaolinite platy particles. Dissolution of kaolinite and recrystallization of halloysite could have occurred in both situations.

Like kaolinites, halloysites have been found to form interstratified phases with smectites. However, halloysite–smectites form under conditions different from those that result in kaolinite–smectites (Delvaux and Herbillon, 1995). Delvaux and Herbillon (1995, and earlier papers cited therein) have generally found interstratified halloysite–smectites in soils formed from volcanic ash. They form under similar (usually alkaline) conditions, which give rise to smectites but where the drainage is less restricted (i.e., more leaching occurs) than for smectite formation (Glassmann and Simonson, 1985; Smith et al., 1987).

There do not appear to be any studies of the form of halloysites and their associations in soils that are similarly detailed to those of soil kaolinites by Singh, Gilkes, and coauthors (Section 20.3.1). However, many electron micrographs, including those of the highly halloysitic Naike and Hamilton soils in New Zealand (formed from strongly weathered tephra) that are shown in Fieldes (1968) and Churchman and Theng (1984), respectively, display mainly tubular particles that are practically all <0.2 μm. Lowe (1986) also found tubes, some split, between ~0.07 and ~0.3 μm in length in similar materials. Furthermore, high values for surface areas of halloysites in soils or halloysite-rich soils from around the world have been recorded by several workers (Quantin et al., 1984; Theng, 1995; Takahashi et al., 2001; Singer et al., 2004). Specific surface areas >100 m^2 g^{-1} were measured for soil halloysites or halloysitic soils in all of the studies cited. These area measurements point to the likelihood that halloysites, like kaolinites, commonly occur as quite small particles in soils. The fineness of their particles very likely reflects compositional or structural features that have limited crystal growth. In the case of the high surface area halloysites studied by Singer et al. (2004), it is likely that the high degree of substitution of Al by Fe and/or Ti introduced strains into the layer structure that limited the size of particles. The clay fractions of two halloysitic soils studied by Takahashi et al. (2001) were found to have high CECs and a high selectivity for K$^+$ in addition to high surface areas, and ^{27}Al-NMR showed that their constituent halloysites had ~2% tetrahedral Al and probably also some Al vacancies and impurity Fe in their octahedral sheets. They contained some Fe as oxides, which could have been present as surface coatings, and some 2:1 Si:Al minerals could also have been present in the clay fraction, even if not detected there, because of their obvious appearance in coarser fractions. While these authors could not reach unequivocal conclusions about the extent to which halloysite per se contributed to the unusual properties of these soils, the dilemma they encountered was the result of the complex mineral assemblages that could involve halloysites in soils and emphasizes how halloysites, like kaolinites, can be bound into multiphase associations in soils.

Halloysites often occur in close associations with iron oxides and oxyhydroxides in soils (Churchman and Theng, 1984; Bakker et al., 1996; Takahashi et al., 2001; Pochet et al., 2007; Etame et al., 2009). Pochet et al. (2007) showed that they can

form stable microaggregates with Fe oxides, and especially ferrihydrite that probably preserve the halloysites in spite of nearby soils being at an advanced state of weathering, which would normally drive the change toward kaolinite in a humid tropical environment.

In a study of soils formed from nephelinite (alkali- and rare-earth-rich lava) in tropical Cameroon, Etame et al. (2009) demonstrated a chemical dependence of the halloysites upon parent minerals: Ce-rich halloysite characterized alteromorphs formed from the mineral phillipsite, Fe-rich halloysite characterized alteromorphs on clinopyroxene, Ca-rich halloysite characterized alteromorphs on hauyne, and K-rich halloysite characterized alteromorphs on leucite. A Ce-rich halloysite (Ce_2O 0.1%) was also identified in saprolite derived from hydrothermally altered nephelinite (Etame et al., 2009).

20.3.3 Occurrence of Illite in Soils

Illites can form in soils by weathering as a result of transformation, in the solid phase, from micas (Section 20.2.4.3, and also, via biota, Section 20.2.5.3) and, like most of the other secondary minerals, they can also precipitate by neogenesis out of solution. There is little doubt that they most commonly form by transformation from primary micas. The degree of transformation they have undergone differs greatly, so that, in younger and less-weathered soils, especially those in arid environments (Section 20.2.5.2), the clay-sized micaceous phases may be mainly a product of comminution of primary micas by physical weathering processes (e.g., Fanning et al., 1989). In this case, the secondary phase may be better described as clay-sized mica rather than as illite. However, the term illite is used quite widely to describe mica-like clay-size minerals in soils, as already noted (Section 20.2.4.3). In all but the youngest or little-weathered soils, the micaceous phase in their clay fraction, hereafter referred to as illite, or illitic, contains some expanded layers; hence, some degree of interstratification of the K-rich illite layers with vermiculite or smectite layers that have become depleted in K through its displacement by hydrated cations. Hence, they are expandable.

Micas, especially muscovite and biotite, are particularly abundant in mica schists and some other metamorphic rocks (Fanning et al., 1989). Mica schists are especially abundant because they originate from the metamorphosis of argillaceous sediments such as shales and slates (ibid.). According to Fairbridge and Bourgeois (1978), shales comprise ~40% to 60% of all sedimentary rocks by volume and ~80% of crustal weathering products. As relatively soft minerals, micas in the schists are readily broken down during transport and sedimentation. Thence, they become important components of shales and slates, the types of sedimentary rocks from which they originated. Hence, illite may originate by inheritance from micas in underlying or nearby sedimentary shales or slates that may ultimately be recycled by metamorphosis into new mica schists (e.g., Garrels and Mackenzie, 1971). Illite in soils formed from these widespread sedimentary rocks is most abundant in the coarse clay (0.2–2 μm) size fraction (Fanning et al., 1989).

On the other hand, illite that has undergone considerable transformation to include expansible 2:1 layers of vermiculite and/or smectite is more likely to occur in the fine clay (<0.2 μm) size fraction (Fanning et al., 1989; Laird et al., 1991; Robert et al., 1991). Studying soil clays derived from the major sedimentary rocks, Robert et al. (1991) found that illite–smectite interstratified phases (I–S) are "the most widespread and representative soil clays," a conclusion that was echoed by Velde and Meunier (2008; see also Section 20.2.5.3). Generally, they are randomly interstratified (Thompson and Ukrainczyk, 2002). Robert et al. (1991) distinguished two types of I–S. One, which they termed "micromicas," may occur as large crystals and have layers with 1 nm periodicity that are separated by "swelling spaces" (Robert et al., 1991). It is a "structural" type of interstratification. The other type consists of random superpositions of elementary particles, "like monolayers," to quote Robert et al. (1991). These authors characterized it as a "textural" type of interstratification, which is the same type as that identified by Nadeau et al. (1984) in the context of diagenetic clay minerals in sandstones.

One of the main conclusions to be drawn from Robert et al.'s (1991) work is that I–S, as common soil clays, differ significantly from reference clays. Among their defining characteristics, they are always multiphase, their smectitic phase is dominantly dioctahedral, and Al-rich, hence beidellitic (Robert et al., 1991), their particles have a very small lateral extension (often 30–50 nm) and a very small number of layers. Furthermore, their smectite component includes partially collapsed layers, and the clays have a high external surface area, particularly relative to their internal surface area (Robert et al., 1991). Laird et al. (1991) studied an I–S mineral that fully occupied fine clay fractions of a soil and found that the smectitic layers comprised a high-charge Fe-rich montmorillonite. This finding is at odds with several reports of soil smectites being more beidellitic, albeit Fe-rich (see Section 20.3.5). Laird et al. (1991) also found that the illitic layers had a low, largely tetrahedral charge, and were dioctahedral. Their layer charge was more typical of a beidellite than an illite. These authors speculated that the illitic layers in the I–S could themselves constitute a breakdown product of illite in the coarse clay fraction or else they could have formed by the collapse of pre-formed beidellite layers, but the evidence available to Laird et al. (1991) favored neither mechanism. Examination of a fine clay (0.02–0.06 μm) fraction by HRTEM in a later study (Laird and Nater, 1993) revealed that this was composed of (1) two-layer elementary illite particles, which were most abundant, (2) one-layer elementary smectite particles, and (3) rare discrete multilayer illite particles. The elementary illite particles could be separated from the smectitic component and were shown to comprise a rectorite-like phase with alternate swelling and nonswelling layers except that, in this case, the swelling and nonswelling layers each had a similar low charge of ~0.47 per formula unit in contrast to rectorite, with ~0.35 for the swelling and ~0.85 for the nonswelling layers (Laird and Nater, 1993). Like Robert et al. (1991), Laird and coauthors identified this I–S mineral phase as being characteristic of soils. Whereas it was identified as a component of an interstratification with smectite by Laird

et al. (1991), the ease of its separation, together with the lack of a 1 nm (10 Å) peak for illite in XRD analysis, indicated that the I–S phase in this fine clay fraction is a "textural" type of interstratification, similar to those identified by Nadeau et al. (1984), and, in soils, by Robert et al. (1991).

Illite can also form by neogenesis. Such illites include some that have formed in close proximity of feldspars, most probably out of solutions bathing the feldspars (Section 20.2.4.2). In many soils in Australia (Norrish and Pickering, 1983), and also in Iran (Mahjoory, 1975) and in some semiarid soils in North America (Nettleton et al., 1970), there is a concentration of illite toward the surface of soils, contrary to the trend in soils where micas are subject to transformation, which leads to increasing vermiculite and smectite at the expense of illite toward soil surfaces. The trend toward more illite in surface soils than at depth suggests that illite may have formed by neogenesis in these soils. Norrish and Pickering (1983) characterized a Fe-rich illite from a deposit ("Muloorina") near a seasonally wet and dry central lake in Australia (Lake Eyre) as a product of neogenesis in the lacustrine environment (although it may not be pedogenic) (Wilson, 1999). Its neogenetic origin was suggested by the very uniform shape and size of its particles, which are almost all ~0.07 μm in diameter (see Churchman, 2000, Figure 1.8a). Similarly sized and shaped particles of illite are also found in a number of soils in various parts of Australia (e.g., Willalooka—see Norrish and Pickering, 1983). The size, shape, and uniformity of these illites are in complete contrast to those originating from micas in rocks. They are more similar in their size and shape to the lacustrine illite from Muloorina (Norrish and Pickering, 1983) than to clay-size breakdown products of rock-derived micas. Berkgaut et al. (1994) found a mineral alongside halloysite in soils formed from pyroclastic layers in a semiarid climate in Israel that comprised very thin crystallites of a randomly interstratified I–S with 70% illite layers and which they considered had formed authigenically. An authigenic origin for illite/mica in soils in Hawaii that was proposed by Swindale and Uehara (1966) was later discredited when oxygen isotope ratios for the fine quartz found alongside the mica in the soils indicated its origin as tropospheric continental dust (Rex et al., 1969) and it was concluded by Syers et al. (1969) that the mica had arrived in the soils in aerosolic dust along with the quartz. Similar findings have been made in other countries such as Japan and New Zealand (e.g., Mizota and Takahashi, 1982; Stewart et al., 1984; Inoue and Sase, 1996; Nagashima et al., 2007; Marx et al., 2009).

20.3.4 Occurrence of Vermiculite in Soils

Most vermiculites in soils have formed by the transformation of micas by weathering (Wilson, 1999), although some form by the analogous transformation of chlorites (Wilson, 1999; Velde and Meunier, 2008) (see also Sections 20.2.4.3 and 20.2.4.4). Dioctahedral vermiculite is much more common in soil clays than its trioctahedral counterpart (Wilson, 1999). This is because, although the first transformation products of trioctahedral biotite (and phlogopite) and also chlorite on weathering

may well be trioctahedral, for example, the regularly interstratified phases, hydrobiotite and chlorite–vermiculite, a variety of structural and composition changes occur within the aluminosilicate layers alongside the loss of K^+ during vermiculitization (see Section 20.2.4.3). The net result of these changes is the loss of Al from the tetrahedral sheet and its gain in the octahedral sheet at the expense of Fe^{2+} and Mg. As a consequence, the layer structure becomes more dioctahedral (Wilson, 2004). Nonetheless, in the North Island of New Zealand, the occurrence of trioctahedral vermiculite in a soil derived from a composite of weathered tephras was attributed to the presence of biotite, which was known to occur in some of the parent tephras because such tephras had been preserved unweathered in layers within sediments in lakes adjacent to the soil (Lowe, 1986).

Although dioctahedral micas are much more stable in the weathering environment than trioctahedral micas, their alteration can also lead eventually to vermiculites, sometimes via regularly interstratified mica–vermiculites, as found in soils formed on mica schists in the South Island of New Zealand (Churchman, 1980). However, where pHs are moderately acid, that is, between about 4.6 and 5.8, organic matter contents are relatively low and there is frequent wetting and drying—all conditions that are conducive to the vermiculitization of micas—Al-hydroxy species are deposited, usually as polymeric cations, in the interlayers of vermiculites (and also some smectites). As a result, vermiculites in soils most often occur with incorporated hydroxyl-Al interlayers (see Churchman, 2000; Wilson, 2004).

Only few reports have considered the possibility of a neogenetic origin for vermiculite. These include those of Smith (1962), who observed that vermiculite replaced feldspars in some Scottish soils of igneous rock origin, and also Barshad and Kishk (1969), who found dioctahedral micas in soils derived from rocks containing no mica. Ildefonse et al. (1979) found that a vermiculite formed as large (up to 150 μm) crystals by crystallization from solution, hence by neogenesis, within a weathered metagabbro-containing plagioclase and amphiboles, hence no micaceous precursor. However, this trioctahedral vermiculite proved to be unstable within the soil above the weathered rock, where it was replaced by a Fe-rich smectite.

20.3.5 Occurrence of Smectite in Soils

Smectites occur in soils either because they are inherited from parent materials, have been formed by neogenesis by crystallization from solutions of the constituents of rocks, or else they are the products of the strong, or long-term, transformation of micas and chlorites. They share the possibility of an inherited origin with most other types of clay minerals. Either (1) preformation in, or prior to, the development of parent materials, for example, sedimentary rocks; (2) a detrital origin from other eroded soils or soft sediments; and arguably also (3) preformation in the soil profile but under previous conditions that differ from those currently prevailing (Buol, 1965), have been responsible for the occurrence of at least a large part of the smectites found in skeletal soils and soils in arid zones and also in some

soils found in strongly leaching climatic regimes (Wilson, 1999). Hence, inheritance may be the main or a major source of smectites in Entisols, Aridisols, and Ultisols and could also have contributed to soils classified into almost all the other orders of *Soil Taxonomy* (Wilson, 1999).

The possible origin of smectites by the transformation of micas and chlorites by acid leaching, and particularly, podzolization, processes was discussed in Sections 20.2.4.3, 20.2.4.4, and 20.2.5.3 (and particularly Section 20.2.5.3.2). The smectites formed in this way, and hence those found in the eluvial horizons of podzols, that is, Spodosols, are beidellitic (Ross and Mortland, 1966; Churchman, 1980; Carnicelli et al., 1997; Wilson, 1999; April et al., 2004), consistent with the effect of acid leaching in selectively removing structural Mg, especially, from 2:1 Si:Al aluminosilicates, which thereby become more aluminous. As the products of changes in the solid state they may also be expected to occur, like most illites (Section 20.3.3), mainly within the coarse clay fractions of soils.

Most typically, however, smectites have been formed in soils by neogenesis from alkaline solutions that have developed under poor drainage. Their formation requires high concentrations of Si and basic cations and is therefore favored typically from basic parent materials. Concentrations of smectites comprising bentonite deposits form under similar conditions, most commonly from large bodies of water, for example, lakes or marine lagoons or shallow-marine embayments into which tephra has fallen or been deposited fluvially (e.g., Millot, 1970; Chamley, 1989; Naish et al., 1993; Velde, 1995; Gardam et al., 2008). Work in New Zealand on detrital glass deposits in shallow-marine Holocene muds showed that the early diagenetic transformation of glass to smectite occurred as a two-stage process initially with diffusion-controlled hydration and dissolution of glass followed by first-order precipitation of smectite (Hodder et al., 1993). Interstitial marine waters of slightly reduced salinity (lower Ca^{2+}, Na^+) and higher concentrations of dissolved silica relative to those in ocean water played a key role in the smectite formation. Rate constants for both the dissolution of glass and the precipitation of smectite were two orders of magnitude greater than those determined for the formation of clay minerals on similar tephra-derived glassy materials in soils (Hodder et al., 1993).

Some of the knowledge of the conditions for the formation of smectites by neogenesis has come from studies of the conditions for their formation in the laboratory (e.g., Harder, 1972, 1977; Siffert, 1978; Farmer, 1997). The requirements for a successful synthesis of a smectite included pH > 7.5 and some Mg and/or Fe in solution. In nature, smectites are often found in calcareous environments, which provide a high pH, and often also where leaching is infrequent or minimal, or where there is an impediment to drainage (e.g., Fieldes and Swindale, 1954; Lowe et al., 1996). However, smectites can form from many types of rocks or geological deposits and minerals, provided that they can provide a sustained supply of the necessary cations and silica (Churchman, 2000).

The origin of smectites occurring in soils is not always clear-cut. While smectites formed by transformation may occur in relatively large particles, as already noted, smectites most often are especially fine-grained materials, a feature more consistent with a neogenetic origin. Somewhat confusingly, Boettinger and Southard (1995) found an aluminous dioctahedral smectite occurring in each of the sand, silt, and clay fractions of an arid zone soil. Although the soils also contained biotite, a trioctahedral vermiculite, and a hydroxyl-interlayered 2:1 Si:Al aluminosilicate, Boettinger and Southard (1995) considered that the smectite in all size fractions was neogenetic, with the coarser particles comprising aggregates of smectite cemented by opaline silica. A geomorphic and salinity gradient transect in another arid environment contained smectite in both its beidellitic and montmorillonitic varieties (Reid et al., 1996). These authors considered that there were multiple origins for the smectite in the soils. The beidellites probably originated from shales by transformation processes, and, while some montmorillonite was inherited, the groundwater chemistry was suitable for some having been neoformed. Studying a toposequence of soils surrounding an alkaline–saline lake in Brazil, Furquim et al. (2008) found smectites in both an upper zone that is largely higher than lake level and also a lower zone that is submerged seasonally by the lake. However, the smectites in the two zones were different structurally and compositionally, pointing to different origins for each of them. In the upper zone, a dioctahedral Fe- and Al-rich ferribeidellite had formed as a result of the transformation of micas whereas in the lower zone, trioctahedral Mg-rich smectites that were characterized as saponitic or stevensitic had formed, apparently by chemical precipitation from the lake, that is, by neogenesis (Furquim et al., 2008).

Most smectites in soils are dioctahedral, including the products of the alteration of Mg-rich serpentinite, where saponite might be expected to form (Wildman et al., 1968). Saponite often does form as a weathering product—for example, within the crystals of altered rocks containing ferromagnesian minerals (Section 20.2.4.1)—but it can give way to dioctahedral smectites in the upper parts of soil profiles (Section 20.2.5.1). Of these, the beidellitic and montmorillonitic varieties of smectites are most common in soils, although nontronites have been found there (Sawhney and Jackson, 1958). Even so, nontronite is thought to be particularly susceptible to attack by complexing agents from roots (Farmer, 1997). Generally, soil smectites have more tetrahedral Al and more octahedral Fe than the type of montmorillonite associated with most bentonites (Wilson, 1987; Weaver, 1989). There appears to be a tendency toward a ferribeidellite composition for smectites in soils, albeit that a given soil smectite is most probably heterogeneous in composition. Petit et al. (1992) found that the smectite in a lateritic profile in Brazil could be described as a true solid solution between nontronite and beidellite endmembers.

Smectites themselves can be subject to alteration and change within soils. As already discussed (Section 20.3.1), smectites can incorporate kaolinite layers to become interstratified kaolinite–smectites (K–S), most probably following the prior adsorption of hydroxyl-Al species into their interlayers (e.g., Ryan and Huertas, 2009). Kaolinite appears to be the ultimate product of this process (Section 20.3.1). Nevertheless, Fisher and Ryan (2006), studying

a chronosequence of soils on fluvial fill terraces in tropical Costa Rica, found that there was a transition with age from smectite-rich to kaolinite-rich soils without any K–S intermediates being formed along the way. The smectite was a beidellite and the kaolinite was disordered. These authors generalized their results and those of others who had studied this transition by suggesting that K–S forms as an intermediate phase in the transition from S to K where the MAP is between ~500 and ~2000 mm, whereas the transition occurs without a K–S intermediate when MAP is more than ~3000 mm. The changes may be more subtle, however, resulting in a change within the composition and structure of the smectite. Thus, a low-charge beidellite inherited from the parent pelitic sediment was converted to a high-change beidellite during the formation of a Vertisol (Righi et al., 1995).

20.3.6 Occurrence of Palygorskite and Sepiolite in Soils

The fibrous 2:1 Si:Mg clay minerals, palygorskite and sepiolite—the so-called hormite minerals—undoubtedly occur in the sedimentary parent materials of many soils containing these minerals; and, until relatively recently, their inheritance from these parent materials was considered to be their source in soils (Singer, 2002). However, both have since been found to form in soils in many countries, including Israel, Syria, Egypt, Morocco, Iraq, Iran, Turkey, Spain, Portugal, China, the United States, Mexico, Australia, South Africa, and Argentina (see summaries in Zelazny and Calhoun, 1977; Singer, 1989, 2002; Churchman, 2000; and reports by Owliaie et al., 2006; Bouza et al., 2007; Kadir and Eren, 2008). Even so, they almost invariably form in calcareous environments (Singer, 2002) and often in calcretes, in particular. Verrecchia and Le Coustumer (1996) have listed many reports of their occurrence in calcretes and there are also later similar reports (e.g., Kadir and Eren, 2008). The main conditions under which they form have been summarized as (1) a fluctuating saline or alkaline groundwater, (2) strong and continuous evaporation, and (3) a sharp textural transition (Singer and Norrish, 1974; Singer, 1989, 2002). A strong textural transition means that water is likely to accumulate at the transitional boundary, hence maintaining a saturated solution from which the hormite minerals can precipitate, under even arid conditions. Calcretes (or caliches) provide such a transition and, hence, these minerals are often found in or below these secondary carbonate concretions. Albeit that palygorskite is most commonly associated with calcareous soils, gypsiferous soils appeared to contain more palygorskite than calcareous soils within the same region in Iran (Khormali and Abtahi, 2003; Owliaie et al., 2006). It appears that an increase in the concentration of Mg that occurred upon the precipitation of gypsum was particularly conducive to the neogenesis of palygorskite (Owliaie et al., 2006).

Chemically, the neogenetic formation of both palygorskite and sepiolite requires considerable magnesium and silicon in a high pH solution. Palygorskite would also require some Al and Fe (Singer, 1989). Although there had been no reproducible synthesis of palygorskite, at least up until Singer (2002), sepiolite has been synthesized many times from alkaline solutions with high activities of Mg, and Si (see, e.g., Churchman, 2000), confirming the conditions for their formation in nature. In nature, the required Mg may originate in dolomite or Mg-containing calcite. The conversion of high-Mg calcite into low-Mg calcite has been observed to accompany palygorskite formation (Singer, 1989, 2002). The required Si may derive from the dissolution of any silicate mineral, including illite and chlorite (Galán et al., 1975; Galán and Castillo, 1984; Dias et al., 1997; Owliaie et al., 2006), smectites (see Singer, 1989; Bouza et al., 2007; Kadir and Eren, 2008), and even quartz (Singer, 1989, 2002). It is not surprising that smectites may give rise to palygorskite and/or sepiolite because the chemical conditions of high [Mg], high [Si], and a high pH are shared among these three mineral types. Bouza et al. (2007) suggested that, as Mg concentration increased with time in calcic and calcic–gypsic horizons in a weathering profile in Argentina, smectite gave way to palygorskite. Nor, therefore, is it surprising that palygorskites and sepiolites often occur together with smectites in soils and may disappear in their favor, as observed by Paquet and Millot (1972), Khormali and Abtahi (2003), Owliaie et al. (2006), and Bouza et al. (2007), for example. Paquet and Millot (1972) suggested that this dissolution and reformation occurs when rainfall rises to a MAP of merely 300 mm. Khormali and Abtahi (2003) found an inverse relationship between the occurrences of palygorskite and smectite with regard to soil available water, measured by the ratio of precipitation to plant transpiration. Smectite was favored over palygorskite at higher values of soil available water. On the other hand, in soils in an irrigated cropping area in India, smectite predominated in the rain-fed soils, but irrigation, which exacerbates salinity and sodicity (and attendant waterlogging), had led to the formation of palygorskite in just 40–50 years (Hillier and Pharande, 2008). It appears that evaporative concentration of the irrigation waters has led to solution conditions more favorable to the formation of palygorskite than smectite. It has also been observed that the highly siliceous environment in which palygorskite and sepiolite form may give rise to an excess of Si in solution, which results in deposits of secondary silica upon their formation (Singer, 1989; Verrecchia and Le Coustumer, 1996). Experiments with nonsoil palygorskite and sepiolite showed that they were unstable, giving rise to kaolinite, within the rhizospheres of common agricultural crops (Khademi and Arocena, 2008). In this situation, the high acidity of the rhizospheres and the extraction of Mg from the minerals by the crops had destabilized them (see also Section 20.2.5.3).

Palygorskite is much more common than sepiolite in soils (Singer 1989, 2002). However, Bouza et al. (2007) found that sepiolite formed chronologically after palygorskite within a mature calcrete.

20.3.7 Occurrence of Iron Oxides in Soils

Iron oxides and oxyhydroxides (generically known as "iron oxides") occur in almost all soils (Allen and Hajek, 1989). They are usually the product of the oxidation of Fe(II) occurring

either within the structure of primary minerals or upon their breakdown by weathering, whereupon the newly formed Fe(III) hydrolyzes (e.g., Churchman, 2000). The resulting iron oxides are essentially insoluble at the pH values encountered in soils and are mainly remobilized by reduction. As we have seen for soils from volcanic materials particularly (Section 20.2.4.6), the specific Fe oxides that occur in a soil depend largely on the environmental conditions under which they were formed.

Following Schwertmann and Taylor (1989), Cornell and Schwertmann (1996), Churchman (2000), Bigham et al. (2002), and Schwertmann (2008), in the main, we can make some generalizations regarding the conditions under which goethite or hematite are formed. Goethite, which is yellow to yellowish brown in color depending partly on particle size, is found in soils almost everywhere. But it is most common in cool and temperate climates and where there are high contents of organic matter. Hematite, by contrast, is most common in aerated soils in generally warmer temperatures in the tropics and subtropics and also in arid and semiarid regions, as well as in xeric (or Mediterranean) climate zones. Hematite is characteristically red in color. High organic matter content favors the formation of goethite over hematite, and it is not uncommon to find soils with yellowish goethitic topsoil over red hematitic subsoil. Goethite also tends to be favored at low pH, hematite at higher pHs. Laboratory syntheses have shown that from ferrihydrite as a starting material, the most goethite was formed at a pH near 4, while the maximum yield of hematite occurred at pHs between 7 and 8. Synthetic work has also shown that hematite is favored over goethite by a high rate of release of Fe into solution. This finding is consistent with the observed occurrence of hematite in a soil on basalt but not in a nearby soil on shale (Kämpf and Schwertmann, 1982). Hematite is the preferred phase where the activity of water is low, as in small pores, and is also the most stable phase thermodynamically in smaller particles (Langmuir and Whittemore, 1971). These latter authors predicted that goethite would be the stable phase in particles >76 nm and hematite in smaller particles. While Al substitution for Fe is common in all Fe oxides, synthetic work has shown that goethite can accommodate more Al in its structure than hematite. Fritsch et al. (2005) explained yellowing toward the surface of a weathering profile on sediments in Brazil by upward changes in both the relative amounts of goethite and hematite and also in the extent of Al substitution of goethite. Hematite and Al-poor goethite that are remnants of prior weathering of the sediments in a different climate have dissolved, with Al-rich goethite forming in their place by recrystallization, according to Fritsch et al. (2005). In some tropical soils, the formation of hematite is at the expense of goethite when temperatures are high, the aeration good, the pH near neutrality, and organic matter is rapidly transformed (Etame et al., 2009).

Poorly crystallized or nanocrystalline ferrihydrite is also widespread in soils, particularly in those formed from tephra, and also in the illuvial or placic B horizons of podzols (see Churchman, 2000, and McDaniel et al., Section 33.3). Its formation is favored by rapid oxidation of Fe and when silicates and organic matter, particularly, but also other ions, are present

in soil solutions to inhibit crystallization of goethite and other Fe oxides, including lepidocrocite (Churchman, 2000; Bigham et al., 2002), and soil ferrihydrites can contain significant amounts of Si (Childs, 1992). Nonetheless, ferrihydrite often also occurs in association with goethite and lepidocrocite (Bigham et al., 2002). In the laboratory, it has been found that ferrihydrite is easily converted to hematite (Schwertmann and Taylor, 1989). Nonetheless, ferrihydrite and hematite are rarely found together in soils, indicating that the conversion is also rapid in nature. Even so, Adamo et al. (1997) found ferrihydrite together with both hematite and goethite in the products of weathering of a volcanic rock by lichens. They appear to occupy different microsites in the altering rock.

The formation of lepidocrocite is favored by seasonally anaerobic conditions in noncalcareous soils. It forms when there is an accumulation of Fe^{2+} together with a slow rate of oxidation (Alekseev et al., 2005). Lepidocrocite is found in ocherous mottles, root mats, and crusts (Cornell and Schwertmann, 1996; Churchman, 2000; Bigham et al., 2002). It is often found in association with goethite. Lepidocrocite was found in all three soils in a hydromorphic sequence in Ohio (Smeck et al., 2002), but in different amounts according to ease of drainage. These authors concluded that the formation of lepidocrocite was favored in horizons that were saturated for between 5% and 50% of the part of the year when the soil temperatures were >5°C. Alekseev et al. (2005) found that lepidocrocite was concentrated in the bottom of the "active" layer immediately above permafrost in Russia. The existence of the permafrost below concentrated solutes in this layer and the low temperature slow oxidation.

Maghemite occurs in soils in the tropics and subtropics, often in association with hematite, and most often in surface soils (Schwertmann and Taylor, 1989; Churchman, 2000; Bigham et al., 2002). A common mode of formation of maghemite appears to be through the heating of other Fe oxides in the presence of organic matter, as occurs in bush and forest fires. Schwertmann and Taylor (1989) suggested that a temperature of between 300°C and 425°C is conducive to the formation of maghemite. It may also form by the oxidation of precursor magnetite in parent materials, according to the authors cited herein. However, a completely different, alternative origin for this magnetic mineral was suggested by Rivers et al. (2004) to explain its occurrence in association with hematite in soils on alluvium that has in-filled low-lying areas in Tennessee. These authors suggested that there had been reduction of Fe(III), either microbial or abiotic, to form magnetite in the hydromorphic soil. Magnetite occurs in many soils but is usually found in the sand and silt fractions rather than the clay fraction and is generally considered to have been inherited from the parent rock. Nonetheless, a partially oxidized form of magnetite was found to occur along with hematite in nodules in an Oxisol in Brazil that has developed from magnetite-free parent materials, so a pedogenic origin has been invoked for the mineral in this soil (Viana et al., 2006). These authors considered that the magnetite in this soil formed under seasonal burning and also that it is becoming converted to hematite by atmospheric oxidation in air. Some

authors (Maher and Taylor, 1988; Geiss and Zanner, 2006) have considered that some magnetite in soils may have had a bacterial origin (see Section 20.2.5.3.5).

Other Fe oxides formed in soils include schwertmannite, from acid sulfate soils (see Section 20.2.5.3.4), and "green rusts," found in a highly hydromorphic soil by Trolard et al. (1997).

Iron oxides can be extremely labile in the soil environment. They are quickly reduced or oxidized when redox conditions change in soils, as they can do intermittently over even quite short time periods (hours to days or weeks) and also seasonally. The activity of microbes can play a central role in the formation and dissolution of iron oxides. A wide variety of microorganisms are involved in these processes and much remains to be understood about their operation (Fortin and Langley, 2005). Suffice it to say here that Fe oxides are often biogenic (see also Section 20.2.5.3). Furthermore, there is widespread recognition that Fe is commonly mobilized in soils by reduction occurring through the activity of microbes in anoxic conditions (Robert and Berthelin, 1986; Schwertmann and Taylor, 1989; Robert and Chenu, 1992). The ensuing reduction occurs along with the oxidation of decomposing biomass.

It is a feature of iron oxides in soils that they are most often closely associated with the other components of soils, including particularly aluminosilicate clay minerals, which as small-charged particles attract Fe oxides and other reactive species to their surfaces and pores. Following the well-accepted convention that (citrate-) dithionite-extractable Fe represents free, or well-crystallized oxides, (acid ammonium) oxalate-extractable Fe represents poorly crystallized oxides, and pyrophosphate-Fe stands

for the metal associated with organic matter, Table 20.5 shows the relative amounts of these forms of Fe and their distribution in relation to aluminosilicate clays in a range of soils, mainly taken from papers in the most recent literature, which have presented data for both different forms of Fe and also estimates of the relative abundance of the phyllosilicates present. The data for selected horizons within one soil of each type are given in Table 20.5. The soils in Table 20.5 represent a wide range of soil orders and lithologies, and soil horizons are also given for each soil. The table shows that there were substantial proportions of iron oxides and Fe-organic complexes in their various forms in all horizons of all the soils examined. They were associated with virtually all of the types of phyllosilicates that occur in soils.

20.3.8 Occurrence of Manganese Oxides in Soils

Manganese oxides are a widespread but usually minor component of soils (McKenzie, 1989; Dixon and White, 2002). Generally, they occur in soils in small particles, leading to poor peaks in XRD. They are more abundant in soils from mafic, that is, basic, rocks than from siliceous materials (Dixon and White, 2002). Because reduced Mn (Mn(II)) is very soluble as a divalent cation and is mobile in soils, they commonly form as coatings on rocks, on ped surfaces, and on other soil particles, as well as in concretions, segregations, pans, and nodules, often with Fe oxides (McKenzie, 1989; Churchman, 2000; Dixon and White, 2002). They are characteristically black in color but give a brown streak.

TABLE 20.5 Occurrence of Iron in Oxides and Oxyhydroxides and in Organic Complexes in a Range of Soils with Different Phyllosilicate Clays

[a] Values of Fe extractable by dithionite (Fe_d), oxalate (Fe_o), and pyrophosphate (Fe_p), also total (Fe_t).

[b] Minerals usually given by first three or four letters of their name, except for quartz (qtz) and HIV; interstratified minerals in brackets: their components often by first letters only; relative amounts of minerals as given in the appropriate reference.

[c] In $CaCl_2$, other pH values in H_2O.
FIGURE 20.11 Scanning electron micrograph of crystals of todorokite, with some kaolin minerals, in infill formed as a result of the weathering of granitic saprolite in Hong Kong. (Photo by Stuart McClure. Reproduced with the permission of the Geotechnical Engineering Office, Civil Engineering Office, Hong Kong.)

Their distinctive appearance, especially in, for example, concretions and nodules, gives a strong indication of prior oxidation, including by seasonal drying as noted earlier in this chapter (e.g., Birkeland, 1999; Vepraskas et al., 2004). Churchman et al. (2010) used their occurrence to trace a history of dehydration, leading to the conditions for the formation of kaolinite rather than halloysite in some saprolites in Hong Kong. Manganese oxides form when conditions favor their oxidation; hence, they are often found in subsoils with a higher pH than the upper layers and are common in calcareous soils. Manganese also occurs as a Mn carbonate (rhodochrosite) in calcareous soils (Dixon and White, 2002).

Among the polymorphs of MnO_2, birnessite, especially, and lithiophorite have most often been identified in soils. However, birnessite occurs in soils as poorly developed crystals and the crystals of birnessite produced by biological oxidation of Mn(II) in the laboratory are similarly poorly developed, as are those precipitated from solutions with a high Si content (Dixon and White, 2002), suggesting that their formation in soils occurs via microbiological oxidation or at an early stage of soil formation, or both (McKenzie, 1989; Dixon and White, 2002). Todorokite has been identified in Texas in nodules from a Vertisol and on the surface of weathered siderite boulders (Dixon and White, 2002) and appeared in large crystals in saprolite on both granite and volcanic tuff in Hong Kong (Churchman et al., 2010), as seen in Figure 20.11, alongside both halloysite tubes and platy kaolinite particles.

20.3.9 Occurrence of Aluminum Hydroxides, Oxyhydroxides, and Oxides in Soils

Gibbsite is the most common of the various hydroxides, oxyhydroxides, and oxides of aluminum in soils (e.g., see Churchman, 2000). It occurs in soils of any age whenever Si is

in low supply. Hence, it occurs under strong leaching. Where there is a gradation in the extent of leaching, often because of an altitudinal change, gibbsite may occur in the most heavily leached soils whereas kaolinite occurs when there is a lesser degree of leaching. This tendency appeared to be the case for temperate mountain soils in South Carolina (Norfleet et al., 1993), as well as for soils in the humid tropics, where gibbsite was dominant in the highlands and kaolinite in the lowlands (Herbillon et al., 1981). In some Oxisols, gibbsite may be most abundant in upper horizons but decrease in concentration with depth (Huang et al., 2002). These authors also pointed out that, in the tropics, particularly, landscapes may be extremely old and the occurrence of gibbsite not necessarily related to the present soil environment. This polygenesis was illustrated in a study by Bhattacharyya et al. (2000), who found gibbsite occurring alongside mica–vermiculite phases containing hydroxy-Al interlayers in an acidic tropical soil in India. However, it has long been considered (Jackson, 1963) that the presence of these latter aluminous interlayers precludes the formation of gibbsite by the so-called antigibbsite effect. Bhattacharyya et al. (2000) explained the presence of gibbsite and these interlayers together by the prior formation of gibbsite, possibly mainly from sillimanite, in an earlier neutral to alkaline pH environment. The aluminous interlayers, by contrast, are products of weathering in the current acidic environment. An apparent contradiction of the "antigibbsite" effect was also seen by Jolicoeur et al. (2000) when they observed each of hydroxyl(-Al) interlayered vermiculite (HIV), kaolinite and/or halloysite, and gibbsite occurring together as pseudomorphs after biotite in scanning electron micrographs of saprolites and soils in central Virginia. They were considered to coexist because they each occupy their own particular microsites and microenvironments of weathering, especially in the vicinity of the altering rock material (Jolicoeur et al., 2000). Gibbsite in soils may also be inherited from saprolites (e.g., Huang et al., 2002; Simas et al., 2005). In these cases, its content decreases toward the surface within the soil profile. In another situation, the co-occurrence of both gibbsite and halloysite, together with kaolinite, goethite, hematite, maghemite, quartz, and cristobalite in old soils formed on strongly weathered andesite or associated alluvium in tropical Costa Rica, was studied by Kleber et al. (2007). They attributed the clay mineral depth-distribution patterns first to intense weathering, with gibbsite increasing with depth as the end product of prolonged tropical weathering, as noted earlier. However, the seemingly paradoxical enrichment of kaolin group minerals and quartz near the soil surface was attributed to ongoing dissolution of Si (quartz being unstable at the silica concentrations necessary for gibbsite formation, namely <0.5 ppm) and its vertical redistribution by a plant-based "biological resilication mechanism" (Kleber et al., 2007, and see also Section 20.2.5.3.3).

Gibbsite may also occur as coatings or infillings of voids in weathered upper soil horizons (e.g., Huang et al., 2002). Gibbsite is also favored if parent materials are rich in Al (e.g., Lowe,

1986), as illustrated by the example of sillimanite within gneiss in Bhattacharyya et al.'s (2000) study.

Among Al oxyhydroxides, boehmite has been identified, along with some other poorly ordered, nanocrystalline, and/or amorphous phases in lateritic profiles, particularly at their surfaces, and also in tropical soils (e.g., Churchman, 2000; Huang et al., 2002). Some may have resulted from the dehydration of gibbsite. Other Al hydroxides, bayerite, nordstrandite, and doyleite, have been identified only rarely in soils (Huang et al., 2002). The Al oxyhydroxide, boehmite, and the Al oxide, corundum, have been reported at the surfaces of ferralitic (lateritic) profiles, whereas corundum has often been seen in the same soils that contain maghemite, for example, in ferralitic duricrusts in Western Australia (Anand and Gilkes, 1987), and these authors proposed that it formed from gibbsite and/or boehmite by dehydration in bushfires. A bushfire origin has also been suggested for maghemite (Section 20.3.7 herein).

20.3.10 Occurrence of Phosphate, Sulfide, and Sulfate Minerals in Soils

Phosphate minerals in soils appear to derive mainly by inheritance or by alteration through weathering of forms of apatite, namely, fluorapatite and hydroxyapatite, from rocks or other geological deposits, or else from reactions between phosphorus fertilizers and soil minerals (Lindsay et al., 1989; Churchman, 2000; Harris, 2002). The products are various forms of phosphates in which the Ca in apatite is substituted, to a greater or lesser degree, by other cations. Hence, there are forms of variscite, where the major cation is Al, strengite (Fe), also barrandite (Al, Fe), vivianite [Fe(II)], crandallite (Ca, Al), plumbogummite (Pb, Al, and other elements), gorceixite (Ba, Al), leucophosphite (K and Fe), along with many other variations (Norrish, 1968; Lindsay et al., 1989; Churchman, 2000; Harris, 2002). A hydrated Al hydroxyl phosphate, wavellite, is the most common Al phosphate in soils derived from phosphoritic marine sediments, which are the most extensive phosphate-rich geological materials at the Earth's surface (Harris, 2002). Nevertheless, phosphates generally occur very sparsely in soils and have to be either concentrated or examined by electron optical methods to be identified (e.g., Norrish, 1968).

Sulfide minerals in soils originate ultimately from the bacterial reduction of sulfate in seawater (Doner and Lynn, 1989; Fanning et al., 2002). They occur in the unoxidized parent materials of soils and are very readily oxidized on exposure to air and drying. Pyrite is the most common sulfide mineral in the unoxidized parent materials. Sulfates, including sulfuric acid, are the products of their oxidation. The reaction of the sulfuric acid thus produced with silicates leads to hydroxyl Fe sulfate minerals, especially jarosite and schwertmannite. These, and their variants, occur typically in acid sulfate soils with their attendant environmental problems (see also Section 20.2.5.3.4). Gypsum occurs in soils as a result of its inheritance from gypsiferous parent materials (or from agricultural application), while barite, of unknown origin, has also been found in some soils, often as a white powder (Fanning et al., 2002).

20.3.11 Occurrence of Pyrophyllite, Talc, and Zeolites in Soils

Both pyrophyllite and talc are rare in soils (Zelazny and White, 1989; Churchman, 2000; Zelazny et al., 2002). As minerals originating at high temperatures and pressures, they are seldom inherited in soils. Pyrophyllite, particularly, is broken down into finer fractions by physical processes (Zelazny et al., 2002). As with other types of minerals, it is the dioctahedral species, pyrophyllite, that is more stable in the soil environment than its trioctahedral counterpart, talc (Zelazny et al., 2002). Generally, talc weathers quickly to nontronite or to Fe oxides. Both pyrophyllite and talc have been protected from breakdown by their encapsulation within Fe oxides in some soils (Zelazny et al., 2002).

Occurrences of zeolites have rarely been reported in soils, but some may have been overlooked because they are generally only present in trace amounts (Boettinger and Ming, 2002). Apart from their inheritance from zeolitic parent materials, such as through hydrothermal alteration (e.g., Kirkman, 1976), some zeolites have formed pedogenically (Ming and Mumpton, 1989; Churchman, 2000; Boettinger and Ming, 2002). The most common pedogenic zeolite is analcime. Along with chabazite, mordenite, natrolite, and phillipsite, analcime has been found to form in salt-affected, alkaline soils, which contain sodium carbonate and have a high pH (Churchman, 2000; Boettinger and Ming, 2002). These soils were both volcanic and nonvolcanic in origin. A number of zeolites have been found in soils in Antarctica that appear to have a secondary origin. These include stilbite, from the weathering of dolerite (Claridge and Campbell, 1968), phillipsite, from tephra dissolved in lakes (Claridge and Campbell, 2008), and chabazite, which has been identified by many workers and which Claridge and Campbell (2008) suggested is quite widespread as a product of thin saline films in intergranular spaces in soils. Other zeolites that have been inherited in soils from parent materials include clinoptilolite, heulandite, gismondine, mordenite, stilbite, and laumontite (Boettinger and Ming, 2002).

20.3.12 Occurrence of Neogenetic Silica in Soils

Because leaching in soil formation results in desilication, silica is often mobilized and then (if not combined with Al for example to form an aluminosilicate clay) can be reprecipitated deeper in the soil environment. Chemically precipitated overgrowths of quartz, particularly on carbonates, are relatively common in soils (Drees et al., 1989; Churchman, 2000). Quartz apparently formed by crystallization out of the dissolution products of microcline (Estoule-Choux et al., 1995; Section 20.2.4.2). In soils across two chronosequences on fluvial deposits in arkosic sands in southern California, Kendrick and Graham (2004) found that the amount of pedogenic, opaline silica (measured by extraction with tiron) increased with duration of soil development from 1.2% to 4.6% of the soil. The loss of Si from primary minerals approximately equaled the gain of secondary (opaline)

silica (Kendrick and Graham, 2004). A number of studies of fine quartz from soils and also shales found a systematic increase in oxygen isotopic ratios with decreasing size, suggesting that the smallest particles of quartz were authigenic (Sridhar et al., 1975; Churchman et al., 1976; Clayton et al., 1978). However, much neogenetic silica in soils occurs in other forms besides quartz (Monger and Kelly, 2002).

Silica cements are common in hardpans or duripans (Chadwick et al., 1987) and also fragipans (Harlan et al., 1977; Marsan and Torrent, 1989) in soils and have been seen to coat surfaces of primary minerals, for example, micas, and to fill gaps in altered minerals including feldspars and micas (Chadwick et al., 1987; Singh and Gilkes, 1993). In the extreme, silica forms massive silcretes in acidic environments (Thiry and Simon-Coinçon, 1996). Secondary silica is sometimes identified as a form of opal, either opal-CT, which is usually inherited from rocks (Munk and Southard, 1993), or opal-A, which is biogenic, and includes plant opals. These are common in some Andisols (Drees et al., 1989) and may be recycled through the death and regrowth of plants (Alexandre et al., 1997). Precipitation of secondary silica may be aided by plant-based processes related to Si uptake and recycling (Henriet et al., 2008) and by evaporation or freezing of soil water. Inorganic silica polymorphs are distinguishable from plant-derived forms of silica, phytoliths, because the latter have more complex shapes inherited from biological cells (Nanzyo, 2007). Farmer et al. (2005) concluded from their study on the concentration and flux of Si in European forest soils (both podzols and acid brown soils) that phytoliths must be the principal immediate sink of silica in soil solution (although weathering is the ultimate source). During the growing season, forest vegetation takes up most of the Si released through weathering of soil minerals and phytolith dissolution and converts it into (new) phytoliths, the latter then becoming the main source of Si leached from the soil during winter rains and spring snowmelt (Farmer et al., 2005). Opals may be transformed to quartz in duripans in soils and also by diagenesis in fossilized wood and sediments (Drees et al., 1989).

Elsass et al. (2000) examined hard plates in laminar horizons and gray mottles at depth in indurated volcanic soils ("tepetates") in Mexico and found strong evidence for the transformation of halloysite to cristobalite via an amorphous opal-A stage. In this case, it appears that the secondary silica phase, first opal-A and then eventually cristobalite, had formed as a result of subtraction of Al from halloysite into solution, rather than through addition of Si from solution as in other cases of the occurrence of secondary Si in soils. Other studies, however, have demonstrated that cristobalite in soils is usually of primary volcanic origin (e.g., Mizota et al., 1987; Wallace, 1991; Mizota and Itoh, 1993). In northern New Zealand, cristobalite isolated from three weathered, halloysitic volcanic soils was identified as alpha cristobalite (opal-C) and was invariably found to be accompanied by tridymite (Wallace, 1991). SEM and oxygen isotope data, along with the highly ordered crystal structure and subhedral grain morphologies, were interpreted to indicate that the cristobalite and tridymite had formed at high temperature from primary volcanic sources (cf. Lowe, 1986; Wallace, 1991).

20.3.13 Occurrence of Titanium and Zirconium Minerals in Soils

Although the major forms of titanium oxide, namely, anatase and rutile, and also their polymorph, brookite, as well as the Fe–Ti minerals, ilmenite, pseudorutile, titanomaghemite, and others, can all form by neogenesis in intensely weathered soils, only anatase and pseudorutile commonly form this way (Milnes and Fitzpatrick, 1989; Churchman, 2000; Fitzpatrick and Chittleborough, 2002). Otherwise, the titanium minerals in soils are inherited from parent materials. Fitzpatrick and Chittleborough (2002) leave open the possibility that zircon, the most common Zr-containing mineral, could also form authigenically in intensely weathered soils. Nevertheless, it is generally inherited from parent materials.

Pseudorutile, which occurs widely in soils, is primarily found there as an alteration product of ilmenite (Fitzpatrick and Chittleborough, 2002). In turn, pseudorutile can dissolve to yield either rutile (Grey and Reid, 1975) or anatase (Anand and Gilkes, 1984). The authigenic formation of titanomaghemite and also ferrian ilmenite may occur by heating Fe–Ti oxides to high temperatures as occurs in bushfires (Fitzpatrick and Chittleborough, 2002). Some Ti^{4+} can become incorporated in other minerals, notably the Fe oxides goethite and hematite, by isomorphous substitution, thereby potentially leading to a reversal of the charge of the Fe oxides (Fitzpatrick and Chittleborough, 2002). Singer et al. (2004) have also found Ti as an isomorphous substitute for Al in halloysite (Section 20.3.2).

20.3.14 Occurrence of Highly Soluble Minerals in Soils

The most common minerals that are laid down following their dissolution from the preformed solid state, whether primary or secondary in origin, and then reprecipitation after evaporation, include calcium carbonate, mainly as calcite, but also as aragonite and Mg calcite (Doner and Grossl, 2002). Magnesite and also dolomite may be formed in that fashion and gypsum probably has a similar origin in arid and semiarid environments (Kohut et al., 1995; Churchman, 2000). Bassanite (or hemihydrite) is usually found in surface soils, indicating its likely evaporative origin (Doner and Grossl, 2002). The highly soluble salts, halides, sulfates, and some carbonates often occur in saline soils and also in arid environments such as Antarctica (Section 20.2.5.2), which is where Bockheim (1997) observed niter ($NaNO_3$) in soils. It is an indication of its extreme aridity that nitrate, borate, chromate, and perchlorate salts have been found in the Atacama desert in Chile (Erickson, 1983; Doner and Grossl, 2002).

20.3.15 Occurrence of Secondary Minerals in Soils: Summary

The main properties of the common types of secondary minerals, and characteristics of their occurrence in soils, are summarized in Table 20.6.

TABLE 20.6 Properties of the Common Types of Secondary Minerals and Characteristics of Their Occurrence in Soils

Group	Common Soil Mineral	Chemical Formula	Related Phases and Names	Specific Surface (m^2g^{-1})	CEC $(cmol_+ kg^{-1})$	Characteristics in Soils	Soils of Common Occurrence
Silicates							
Kaolin	Kaolinite	$Al_2Si_2O_5(OH)_4$	Dickite, nacrite	6–40	0–8	Very small euhedral particles, associated with much Fe	Widespread, high in well-weathered soils
	Halloysite	$Al_2Si_2O_5(OH)_4 \cdot 2H_2O$	Endellite[a], metahalloysite[a] 1.0 nm (10 Å) halloysite (= hydrated phase), 0.7 nm (7 Å) halloysite (= dehydrated phase)	20–60	5–10	Generally small tubular or spheroidal particles, associated with Fe	Where humid, especially from tephra (including volcanic ash)
Interstratified kaolin	Kaolinite–smectite	Variable, depending on proportions of K:S	Halloysite–smectite	Unknown	30–70		Moderately drained
Mica	Illite	$K_{0.6}(Ca,Na)_{0.1}Si_{3.4}Al_2 Fe^{III}Mg_{0.2}O_{10}(OH)_2$		55–195	10–40		Widespread, especially weakly weathered soils
Interstratified mica	Illite–vermiculite	Variable, depending on proportions of I, V	Mica–vermiculite	Unknown	Unknown	Usually regular, mica–vermiculite	Eluvial horizons of podzols
	Illite–smectite	Variable, depending on proportions of I, S	Mica–smectite	Unknown	Unknown	Either regular, mica–beidellite, or random, poss. with single layers	Regular: eluvial horizons of podzols. Random: very widespread, often in agricultural soils
Interstratified chlorite	Chlorite–vermiculite	Variable, depending on proportions of C, V	Corrensite	Unknown	Unknown		At very early stages of weathering
	Chlorite–smectite	Variable, depending on proportions of C, S	Chlorite-swelling chlorite	Unknown	Unknown		At very early stages of weathering
Vermiculite	(dioctahedral)	$K_{0.2}Ca_{0.1}Si_{3.2}Al_{0.8}$ $(Al_{1.6}Fe_{0.2}Mg_{0.2})$ $(Al_{1.5}[OH]_4)O_{10}(OH)_2$	Pedogenic chlorite, HIV, 2:1–2:2 intergrade, chloritized vermiculite	Unknown	pH-variable		Leached, mildly acid soils
	(trioctahedral)	$M_x^{II}(Mg,Fe)_3$ (Al_xSi_{4-x}) $O_{10}(OH)_2 \cdot 4H_2O$		50–150	100–210		Early stages of weathering, especially below soil zone
Interlayered	Pedogenic chlorite	Variable, depending on whether layers are vermiculite or smectite and interlayered species	HIV, 2:1–2:2 intergrade, chloritized vermiculite HIS, chloritized smectite	Unknown	Unknown		Intermediate pHs, ~4.6 to 5.8, with wetting and drying, low organic matter
Smectite	Beidellite	$M_{0.25}^{II}Si_{3.5}Al_{2.5}$ $O_{10}(OH)_2$	Nontronite, hisingerite[a], saponite	15–160 Interlayer ~800 (all smectites)	45–160 (all smectites)	Often occur as ferribeidellites in soils, but heterogeneous	More beidellitic in acid-leached horizons; otherwise where drainage retarded and pH high
	Montmorillonite	$M_{0.25}^{II}Si_4Al_{1.5}Mg_{0.5}O_{10}(OH)_2$	Stevensite, hectorite				
	(Palagonite)	Prob. variable		Unknown	Unknown	Nanocrystalline precursors of smectites	Early weathering products of basaltic volcanic glass

Hormite	Palygorskite	$Si_8Mg_5O_{20}(OH)_2 (OH_2)_4 \cdot 4H_2O$	Attapulgite[a]	140–190	3–30	Fibrous	In dry, usually calcareous regions, near textural transition in profile (both)
	Sepiolite	$Si_{12}Mg_8O_{30}(OH)_2 (OH_2)_4 \cdot 8H_2O$		Generally 260–330	20–45	Fibrous	
Al–Si	Imogolite	$SiO_2 \cdot Al_2O_3 \cdot 2H_2O$; Si tetrahedra within Al octahedral in tube		1500	pH-variable	Nanocrystalline: bundles of very thin hollow threads or tubules (nanotubes)	Limited, mainly from pumice, also podzol illuvial B horizons and related soil horizons
	Allophanes	Al:Si 2:1—1:1; variable between imogolite and allophane		700–1500	pH-variable	Nanocrystalline: very small spherules (nanospheres or nanoballs); closely associated with organic matter	From tephra (including volcanic ash) and in podzol illuvial B horizons, and in some other materials that are strongly leached
Nonsilicates							
Al hydroxide, oxyhydroxide, oxide	Gibbsite	$Al(OH)_3$	Bayerite, nordstrandite, doyleite, α, or γ alumina trihydrate	Unknown	pH-variable	Hexagonal crystals	Where Si low, especially in strongly leached soils
	Boehmite	$\alpha AlOOH$	Diaspore, α, or γ alumina monohydrate	Unknown, prob. high	pH-variable		Strongly weathered soil materials or soils, ferricrete (laterite), bauxite
Fe oxyhydroxide, oxide	Goethite	$\alpha FeOOH$	Limonite[a]	14–77	pH-variable	Yellow to yellow-brown color	Widespread—most common iron "oxide"
	Lepidocrocite	$\gamma FeOOH$	Akagenéite	Unknown, prob. high	pH-variable	Orange color	Noncalcareous soils that are seasonally anaerobic
	Hematite	αFe_2O_3		35–45	pH-variable	Bright red color	Soils of warmer climates
	Maghemite	γFe_2O_3	Titanomagnetite	Unknown, prob. high	pH-variable	Ferrimagnetic	Tropical and subtropical soils, from fires, poss. from bacteria
	Ferrihydrite	$Fe_5HO_8 \cdot 4H_2O$	Feroxyhite	200–500	pH-variable	Nanocrystalline: spherical nanoparticles, pinkish to yellowish-red color	Widespread, where Fe(II) is oxidized rapidly
Mn oxide	Birnessite	$Na_{0.7}Ca_{0.3}Mn_7O_{14} \cdot 2.8H_2O$	Todorokite, hollandite, lithiophorite, pyrolusite	Unknown, prob. high	pH-variable	(Blue-) black color	Widespread but usually minor component; in concretions, segregations, pans and nodules in subsoils
Sulfide	Pyrite	FeS_2	Mackinawite, greigite, pyrrhotite	Unknown	Unknown		Coastal regions and from some sediments when unoxidized
Sulfate	Gypsum	$CaSO_4$	Bassanite, anhydrite, barite ($BaSO_4$)	Unknown	Unknown		Often in desert soils
	Jarosite	$KFe_3(OH)_6(SO_4)_2$	Natrojaroite, schwertmannite	Unknown	Unknown		Acid sulfate soils or strongly acid seepages
Phosphate	Plumbogummite	$PbAl_3(PO_4)_2(OH)_5 \cdot 2H_2O$	Variscite (Al), strengite (Fe), crandallite (Ca), gorceixite (Ba)	Unknown	Unknown		Rare, from breakdown of rock phosphate
Ti oxide	Anatase	TiO_2		Unknown	Unknown		Widespread, in small amounts
Chloride	Halite	$NaCl$		Unknown	Unknown		Seasonally dry saline soils

20.4 Influence of Mode of Formation upon Predictions of Properties of Soils from Their Clay Mineralogy

20.4.1 Introduction: The Role of Mineralogy in Soil Science

Broadly speaking, soils are studied and interpreted either as products of the natural environment, which reflect their environmental history, or else as useful materials in which to grow plants or for removing and cleaning wastes and pollutants or providing resources or "environmental services" such as regulating water flow. Minerals, and particularly secondary (clay) minerals, have likewise been regarded and assessed either as indicators of the origin of soils and of changes, which have occurred in them through their development, or else as the most reactive inorganic components of soils. For the latter role, it has often been considered that knowledge of the properties of clay minerals would be useful in predicting the agronomic and adsorptive capacities of soils. However, several indicators have suggested that soil mineralogy has come to be regarded as less important to practitioners of the discipline of soil science in recent years than its other main subdisciplines such as soil chemistry, soil physics, soil biology, pedology, spatial analysis, and pedometrics, let alone the major applied aspects of soil fertility and soil pollution, than once was the case. For example, an analysis of papers that were published in the first 100 volumes of *Geoderma*, spanning from 1967 to 2001, showed a sharp decline in those on soil mineralogy, but either a rise or no significant decline in those from the other main subdivisions of soil science (Hartemink et al., 2001). It appears that mineralogical studies have been able to make fewer worthwhile contributions in comparison with those of other aspects of soil science than in earlier times. Nonetheless, the survey of the literature for this chapter suggests that a great deal of research continues to be undertaken into the origin of secondary minerals in soils and also, to some extent, into their mode of occurrence within soils. This new work includes the recognition that the clay fractions of many soils and associated materials contain nanominerals (including allophanes and ferrihydrite as discussed earlier), which confer unique properties and reactivities (Theng and Yuan, 2008; Waychunas and Zhang, 2008). Nanoscale minerals are defined as having at least one dimension in the nanorange, that is, 1–100 nm (Hochella, 2008). Nanoscience is now regarded as being a critically important new offshoot of more traditional colloid or clay mineralogy, and the growth rate of articles being published on nanoparticle science (relevant to the geosciences) is around 10% per year, about triple the average growth rates of all scientific disciplines over a 5-year period (Hochella, 2008).

20.4.2 Contributions of Classical Clay Mineralogy toward Explanations of Soil Properties

Clay mineralogy is a relatively young area of study. Up until 1929, with the publication of a pioneering bulletin by Hendricks and Fry on the X-ray examination of soil clays that was quickly followed by a journal paper (Hendricks and Fry, 1930), most had regarded clays, which were largely indistinct in optical microscopes, as being amorphous (Cady and Flach, 1997). XRD was very successful in determining that much of the clay-sized inorganic material in soils was composed of regular crystals like those that had been identified in minerals in rocks or other geological deposits. Although many other instrumental techniques have been applied to their identification and characterization over the intervening years, the search for and refinement of crystal structures has remained a major pursuit of clay mineralogists and XRD has continued to be their major workhorse. Its use, whether for structural determination or as the major instrument for the identification of clay-sized minerals in soils, has defined classical clay mineralogy.

Among the most useful roles promised for classical clay mineralogy in soil studies has been that of explaining the abundance of certain plant nutrients by soils. Probably chief among these has been potassium, with K-micas apparently providing a labile source of K^+ (e.g., Norrish, 1973; Loveland, 1984). Loveland et al. (1999), in writing a history of clay mineralogy at the Rothamsted Experimental Station from 1934 to 1988, attempted to identify the reasons why considerable effort was put into this area of soil science at one of the world's leading centers of soil research. At its outset in 1934, clay mineralogy was supposed to provide an understanding of the physicochemical behavior of the soil clay fraction mainly with respect to "the sorption and desorption of water and nutrients, with their practical consequence for soil workability and plant nutrient supply" (Loveland et al., 1999, p. 165). Its most important contributions are judged by these authors to have been in the identification of the phenomenon of interstratified minerals and the behavior of soil K. Even so, in spite of a large number of British studies, at Rothamsted and elsewhere in the United Kingdom, on the influence of clay mineralogy on the potassium-supplying power of soils, Loveland (1984, p. 700) stated that "none were successful in using clay mineralogy as a reasonably exact predictive tool for this property." Loveland (1984) concluded that (classical) clay mineralogy related better to geotechnical properties of soils than to their nutrient-supplying power. In apparent contrast, the K-supplying power of soils formed from quartzo-feldpathic loess or alluvium and colluvium from sedimentary rocks in New Zealand showed a close relationship to the mica contents of their clay fractions (Surapaneni et al., 2002). Barré et al. (2008), studying two French soils and one from the United States, also found that micaceous minerals in soil clay-size fractions serve as reservoirs for potassium. However, they found that the ability of soils to supply K to plants, and also to extract K when it was in excess, through fertilizer additions, could only be fully understood when the micaceous minerals were delineated into five different types. These were a well-crystallized illite, a poorly crystallized illite, a highly smectitic interstratification of illite and smectite and its highly illitic counterpart, and a soil vermiculite. These could be separately determined quantitatively, relative to one another, by decomposition of the XRD peak profile, following Lanson's (1997) procedure. Barré et al. (2008) claimed that the approach

could be used to predict the K release potential of soils generally and Velde and Barré (2010) provide many examples of the utility of this approach. It may offer a wider applicability than the relationships developed by Surapaneni et al. (2002) for soils, which have quite similar origins in just one country.

20.4.3 Potential of Classical Clay Mineralogy for Explaining Soil Properties

A different mineralogical approach using X-ray fluorescence (XRF) analyses of whole soils and also analyses of acid digests of soils by inductively coupled plasma mass spectroscopy (ICP-MS) was used to determine the normative mineralogies of forest soils in Finland at the early stages of weathering in order to explore the availability of reserves of the nutrients Ca and Mg (Starr and Lindroos, 2006). At the earliest stages of weathering, it is the extent of alteration of primary minerals rather than the nature of any secondary products that is the mineralogical characteristic that best relates to agronomic properties. Clay mineralogy per se is of little predictive use when clays have hardly been formed. For soils in most of the world's agricultural areas, however, the overwhelming contribution to the surface area of the soils, as well as virtually all of their charge, arises from material in their clay fraction (e.g., Gilkes, 1990; Churchman, 2006). The highly reactive clay-size material includes both organic and inorganic components, and it is the task of soil clay mineralogists to understand the source of the contribution made by the inorganic components. Gilkes (1990) noted that Norrish and coworkers recognized some time ago that secondary minerals in soils could hold and, when required, supply other important nutrients besides K for plants. These included manganese oxides, for cobalt (Adams et al., 1969), and iron oxides, for phosphorus (Norrish and Rosser, 1983). Classical clay mineralogy, using XRD, may be capable of detecting the presence of these oxides in soils provided that they are reasonably well crystallized, and that their XRD peaks are not masked by stronger peaks for other minerals. Even so, it is not simply their presence, but rather their detailed structural, chemical, and physical characteristics, as well as their associations with other soil entities that govern the reactivities—both chemical and physical—of these and other oxides, hydroxides, and oxyhydroxides, as well as of aluminosilicate phases in soils. Furthermore, much evidence points to the idea that metal oxides (used generally hereafter to include both oxyhydroxides and hydroxides) play a role in determining many of the useful properties of many soils that is out of proportion to their content in the soils. This status includes the indication from several earlier studies, van Raij and Peech (1972) and also Gallez et al. (1976), among them, that the surface charge–pH curves of many tropical soils show the characteristic features of metallic oxides, which have a pH-dependent variable charge. Similarly, nanocrystalline aluminosilicates such as allophane also make an extremely disproportionate contribution to both the surface area and reactivity of soils, including through a pH-dependent variable charge, even where only small amounts are present (e.g., Lowe, 1995; McDaniel et al., Section 33.3). In an effort to try to

reconcile studies that have found that Fe oxides play a positive role in aggregation in soils (e.g., Colombo and Torrent, 1991; Oades and Waters, 1991) with others in which Fe oxides do not appear to affect aggregate stabilities (e.g., Deshpande et al., 1968; Borggaard, 1983), Duiker et al. (2003) found that their effect depended upon their crystallinity. The most poorly crystalline Fe oxides played an important role along with organic matter in aggregate stabilization and, where organic matter contents were low, as in B horizons, their contributions to indices of aggregation were found to equal or exceed that of organic matter (Duiker et al., 2003), confirming similar trends seen by Churchman and Tate (1987) for the particular case of soils formed on volcanic ash. However, Al oxides may be more important than Fe oxides in governing both aggregate stability and also P adsorption in some soils. This relationship appeared to hold for Latosols in Brazil (Schaefer et al., 2004). In one soil, at least, an amorphous Al-hydroxy phase appeared to play an important role in both aggregation and P adsorption.

One property of soils that particularly demands explanation and, if possible, prediction, at this time is that of the capacity of soils to adsorb and retain organic carbon. The momentum for work to be done in this area comes from growing community concerns about the increased levels of carbon dioxide in the atmosphere, its links to global warming, and the role that soils may be able to play in sequestering excess carbon and isolating it from the atmosphere (Amundson, 2001; Kahle et al., 2002a). As Kahle et al. (2002a) pointed out, many workers have discovered relationships between clay content and carbon content, although it is noteworthy that not all have found such a link, for reasons we will discuss herein. Nevertheless, it has long been known (e.g., Greenland, 1965) that clays and organic matter can be strongly associated in soils. Even so, it has long been appreciated (e.g., Hamblin and Greenland, 1977) that the links between clays and organic matter can occur through Fe and Al oxides. Mikutta et al. (2005) and also Kleber et al. (2005) reported that for acid subsoils under forest and representing a wide range of parent rock types and rainfall, poorly crystalline oxides of both Fe and Al provided the strongest binding agents for organic matter. According to Mikutta et al. (2005), poorly crystalline to nanocrystalline Fe oxides such as ferrihydrite were particularly effective for stabilizing organic C in these soils. It is also significant that these authors found that none of the factors of clay content, namely, the specific surface area of the minerals as determined by nitrogen gas adsorption using the BET equation, total iron oxide content, or the nature of the phyllosilicate clays, was a good predictor of the ability of the soils to stabilize C. Their results confirmed those of Percival et al. (2000) who correlated the organic C contents of 167 New Zealand soils with several soil properties and found they showed significant linear relationships with oxalate-extractable Si and Al, which together represent allophane content, and also with pyrophosphate-extractable Al, which represents Al associated with organic matter, that is, "Al-humus complexes," but found no relationship with total clay content. Rasmussen et al. (2005), also studying forest soils, came to similar conclusions as those of Percival et al. (2000). In a different,

tropical environment, but again studying forest soils on volcanic ash, Basile-Doelsch et al. (2005) found that organic C in buried horizons was strongly bound in abundant amounts in soils containing allophane, whereas buried horizons with large amounts of crystalline minerals, including feldspars and gibbsite, had little capacity for C storage. The studies by Mikutta et al. (2005) and also Kleber et al. (2005), which were on samples devoid of allophane, showed that it is not the particular occurrence of allophane or even of ferrihydrite that is necessary to provide strong links to organic C. Rather it is the capacity of poorly crystalline or nanocrystalline minerals of both Fe and Al to provide singly coordinated hydroxyl groups that are able to participate in ligand exchange with organic functional groups, which ensures strong associations with organic C, according to Kleber and coworkers in the two related 2005 reports. This generalization also bears out the results of experiments by Kahle et al. (2004) in which dissolved organic carbon (DOC) was added to soil clays that had been depleted of organic C and also to "type" phyllosilicates from nonsoil sources. This experiment showed that soil clays adsorbed much more DOC than the type clay minerals and that the difference appeared to be due to pedogenic oxides, mainly of Fe, which provide reactive hydroxyl groups for DOC sorption. In the case of some tropical soils, Barthès et al. (2008) found that organic C content and also aggregate stability were promoted when sesquioxides, especially goethite and hematite, in the soils included substitutions by Al, which increased their specific surface areas.

One of the common characteristics of Andisols is accumulation of relatively large quantities of organic matter, both in the allophanic (moderate pH) and in the nonallophanic Andisols (low pH). Allophanic Andisols may contain ~10% or more C, whereas nonallophanic andisols (dominated by Al- and/or Fe-humus

complexes) may contain as much as ~30% of C. However, the residence time of C in soils containing allophane, as measured by ^{14}C, is much greater than that of other soils (Figure 20.12; also see Parfitt, 2009).

Albeit that the studies by Kleber and coworkers on acid subsoils showed no relationship between stabilized organic C and the surface area of minerals in the soils, extent of surface intuitively appears likely to be able to explain the capacity of soils for organic C, and several workers have proposed such a relationship (e.g., Saggar et al., 1996; Kaiser and Guggenberger, 2000; Eusterhues et al., 2005). Indeed, to illustrate the point that different soils lead to different generalizations about the relationship between C content and surface area, and, incidentally, forms of Fe in soils, Kahle et al. (2002b) found that a combination of specific surface area and total (i.e., dithionite-extractable) Fe oxide content predicted C content almost completely, with an R^2 of 0.96, in the topsoils of a set of illitic soils with more or less neutral pHs that had been farmed since Medieval times. The surface areas were determined using the sorption of nonreactive nitrogen gas and hence gave a good measure of external surface (e.g., Churchman and Burke, 1991). Using isotopically labeled plant material, Saggar et al. (1996) found that its residence time during its initial decomposition in soils correlated well with the surface area of the soil as measured by the adsorption of p-nitrophenol. It is noteworthy that it was this particular (p-nitrophenol adsorption) method that showed a good relationship with organic C retained in this case. Like Churchman and Burke (1991), these authors also tried to explain soil properties (organic C uptake in this instance) by the sum of the surface areas from the literature for the mineral components of the soils and also largely failed. By contrast, consideration of the specific surface areas (SSAs) from N_2 sorption of different soil types in relation to those calculated
FIGURE 20.12 Model showing slower rates of incorporation and turnover of organic C using bomb-derived ^{14}C in an allophanic soil (Egmont series) compared with those of a soil without appreciable allophane (Tokomaru series) under similar climate and land use in New Zealand. (Based on Baisden, W.T., R.L. Parfitt, and C.W. Ross. 2010. Radiocarbon evidence for contrasting soil carbon dynamics in an Andisol and non-Andisol pasture soil comparison. J. Integr. Field Sci. 7:59–64.) RT, residence time of carbon. (Modified diagram from Parfitt, R.L. 2009. Allophane and imogolite: Role in soil biogeochemical processes. Clay Miner. 44:135–155. With permission of The Mineralogical Society of Great Britain and Ireland.)

for their constituent Fe oxides and allophane led Eusterhues et al. (2005) to conclude that almost all mineral-associated organic matter in soils is bound to Fe oxides. Churchman and Burke (1991) generally found that the strength of the relationship between a soil property and surface area depended upon the technique chosen to measure surface area (they compared N_2 gas sorption, with sorption of polar liquids ethylene glycol monoethyl ether [EGME] and water) and the relevance of the adsorbate to the soil property of interest. A good relationship between a particular soil property and surface area deduced from the sorption of a particular adsorbate shows that the property and the capacity of the surface for the adsorbate have similar causes but does not show that the property relates to a generic measure of surface area, which most probably does not exist.

To further complicate the nature of the relationship between minerals and organic C in soils, it is noted that a study of the energetics of organic C sorption by Mayer and Xing (2001) revealed that minerals appeared to be occluded by OM, rather than the OM being adsorbed by minerals, and that micropores were likely to be responsible for some of the associations. Kaiser and Guggenberger (2003) suggested that OM was preferentially adsorbed within, or at the mouths of, micropores <2 nm in diameter in iron oxides in soils. The results of density fractionations combined with TEM led Chenu and Plante (2006) to conclude that most OM was stabilized in soils by close associations with clays in very small microaggregates, either through adsorption or by entrapment. Wan et al. (2007) mapped organic carbon along with other elements in different soils using scanning transmission X-ray microscopy (STXM) and found that OM exists as distinct particles within microaggregates more often than as coatings on minerals. Using small-angle X-ray scattering to directly observe pores and their constituents, McCarthy et al. (2008) found that most OM was held within pores, although not necessarily very small pores, in formerly cultivated soils that had been restored to tallgrass prairie. Their main conclusion was that OM was encapsulated, rather than adsorbed, by minerals. According to Richards et al. (2009), it is the occurrence of aggregates, rather than the abundance of oxides of Fe and Al, that enabled the stabilization of OM in oxide-rich soils in the Australian subtropics. As a result, more organic C was

held in soils under rainforest and pastures than in those under pine plantations. Furthermore, Spielvogel et al. (2008), like many others (e.g., Kleber et al., 2005; Mikutta et al., 2005; Rasmussen et al., 2005), examined the causes of OM stabilization in acidic forest soils, but arrived at the conclusion that, while Fe and Al oxides, and, particularly, their poorly crystalline to nanocrystalline varieties, were responsible for stabilization, they are bound to, and stabilize, only a specific fraction of the OM. This fraction was concentrated in O/N-alkyl C and microbially derived sugars compared with the nonstabilized remainder (Spielvogel et al., 2008).

It, therefore, appears likely that the properties of the mineral fraction, which control the uptake and retention of organic C by soils, vary greatly between soils. Any generalization is likely to founder when applied to a particular case. Indeed, following Kaiser and Guggenberger (2003), Chenu and Plante (2006), Wan et al. (2007), McCarthy et al. (2008), and Richards et al. (2009), we suggest that it may be that the properties of minerals that are most important are those that enable them to form pores or aggregates for encapsulating OM, and their identification probably defies a simple summary. At the most, it can probably be concluded only that a number of possible characteristics of the mineral phases are likely to influence the capacity of soils to stabilize C and it remains for practice to show which are more important than the others in each instance. A possible list of such characteristics is given in Table 20.7. A number of studies have attempted, like Churchman and Burke (1991) and Saggar et al. (1996) with specific surface area, to explain soil properties by the sum of the contributions from their different mineral (and also, sometimes, organic) components. Properties that were proposed for explanation in this way have included CEC (Seybold et al., 2005). CECs could be largely explained within mineralogical groupings from *Soil Taxonomy* when organic C was included. Churchman and Burke (1991) also found good relationships between CECs and a measure of water retention within mineralogical groupings of soils with low carbon contents.

Together, these results suggested that the use of classical clay mineralogy to group mineralogically similar soils may be reasonably successful for predicting CECs. In addition, close comparisons of experimental and theoretical titration curves indicated

TABLE 20.7 Characteristics of Mineral Phases That Have Helped to Explain the Capacity of Various Soils for the Uptake and Retention of Organic Carbon

Most Relevant Mineral Phase and/or Property	Soil	References
Fe and Al oxides	Silty soils	Hamblin and Greenland (1977)
Allophane + pyrophosphate–Al	167 soils (from throughout New Zealand)	Percival et al. (2000)
Specific surface area + total Fe oxides	Neutral illitic topsoils	Kahle et al. (2002b)
Pedogenic oxides, mainly of Fe	Range of forest and arable soils with range of mineralogy	Kahle et al. (2004)
Fe oxides	Cambisol and podzol under forest (acid)	Eusterhues et al. (2005)
Poorly crystalline (or nanocrystalline) Fe and Al oxides, especially ferrihydrite	Acid subsoils under forest	Kleber et al. (2005) and Mikutta et al. (2005)
Allophane	Volcanic ash soils under forest	Basile-Doelsch et al. (2005)
Al-substituted Fe oxides	Tropical soils	Barthès et al. (2008)
Fe and Al oxides	Acidic forest soils	Spielvogel et al. (2008)

that surface charge densities of some soils from Argentina were apparently successfully modeled by the sum of those of their constituent mineral phases when the mineralogical compositions of the soils were determined by a Rietveld approach (Taubaso et al., 2004). This result suggests further that the charges on soils may be largely additive of those on their constituent clay-size minerals. Nonetheless, this and earlier work by a group from the same laboratory (Torres Sanchez et al., 2001) showed that there was a mismatch between the point of zero net charge (PZNC) and the isoelectric point for those soils in which Fe oxides were adsorbed on to phyllosilicate clays. Hence, the diffusion behavior of these soils, which relates to their isoelectric points (IEPs), cannot be simply regarded as additive of their component colloidal minerals but must account also for their associations with one another.

While there has been some success with the modeling of charge characteristics, both permanent (Seybold et al., 2005) and variable (Taubaso et al., 2004) from the mineral composition of soils, mineral composition patently could not describe organic matter stabilization by minerals in soils. However, in some cases, at least (Kahle et al., 2004; Kleber et al., 2005; Mikutta et al., 2005; see also Table 20.7), it appears that some functional groups, singly coordinated hydroxyl groups in particular, play a crucial role in binding natural organic compounds—albeit perhaps only a fraction of the total soil organic matter, following Spielvogel et al. (2008). Therefore, the question arises as to whether more accurate descriptions of mineral–organic associations, and of reactions of other species, for example, anions such as phosphates and arsenates with mineral surfaces, might be better made on the basis of the amount of the important functional groups present, by an approach that is analogous to that taken by modern soil organic matter studies using, for example, ^{13}C-NMR and FTIR spectral analyses (e.g., Baldock and Nelson, 2000).

Gustafsson (2001) used a "component additivity" approach in an attempt to predict, or model the adsorption of arsenate in competition with sulfate, silicic acid, and phosphate on allophane and also ferrihydrite, and tested the results against experimental data for the adsorption on the spodic horizon of a Swedish soil that contained both ferrihydrite and allophane but little organic matter. Although this approach led to results that were qualitatively realistic, Gustafsson (2001) nevertheless concluded that the approach is probably impractical, partly, at least, because it relies on the assumption that the properties of allophane and ferrihydrite in real soils can be approximated by those of gibbsite and ferrihydrite synthesized in the laboratory. Among many others, Gérard et al. (2007) have shown that this assumption is simplistic and unrealistic. In the particular case that these last authors studied, allophane formed on basalt in the Azores was found to have an especially complex genesis, leading to allophanic products with a large range of compositions. Gérard et al. (2007) claimed that not all of the allophane formed was the product of recrystallization from solution, describing some of it as "alteromorphs after lapilli or pumice," which result from the leaching of Si and cations from these materials. The products encompassed a compositional range from pure aluminosilicates to Fe- and Ti-enriched aluminosilicates and included

varieties of both Al-rich and Si-rich allophanes, while the soils also contained many different iron phases, ferrihydrite, hematite, and also "iddingsite" (see Section 20.2.4.1), among them.

The component additivity modeling approach adopted by Gustafsson (2001) foundered because allophanes and ferrihydrite, as they are found in soils, differ in many important respects from either natural minerals from nonsoil environments such as the "stream deposit allophane" (Childs et al., 1990; Parfitt, 1990) or synthetic minerals of the same name, in the case of ferrihydrite. They are unique to soils, and they also show variations within their type. A number of other minerals are unique, or almost unique, to soil environments, and the properties and reactivities of these, also, cannot be modeled upon those of minerals found in nonsoil environments. These include fully or partially expanded 2:1 Si:Al aluminosilicates with hydroxyl-Al interlayers (see Section 20.2.4.3), which may show even seasonal changes in the soil biological system (see Section 20.2.5.3). They also include interstratified phases in their various manifestations. Velde and Meunier (2008) have characterized those of illite and smectite as being "peculiar to the soil environment" (Section 20.2.5.3.1), as well as being "the most widespread and representative soils clays." By the same token, smectites found in soils have been characterized as being commonly ferribeidellitic in composition and, therefore, are quite different from the bentonites from which typical nonsoil montmorillonites have usually been extracted to serve as models for smectites in soils (Section 20.3.5).

However, it is not just the particular composition, structure, and arrangement of layers of the minerals in soils that often make them different from so-called typical minerals taken from nonsoil sources. They differ from the latter partly because important physical properties of secondary minerals in soils are generally different from those of nonsoil minerals. Studies of soil kaolinites from soils on three continents by Singh, Gilkes, and coworkers (Section 20.3.1), a number of studies of soil halloysites (Section 20.3.2), and a study of iron oxides by Trakoonyingcharoen et al. (2006) (Section 20.3.7), have focused specifically on the sizes and sometimes also surface areas of the particles. The studies generally concluded that those of the soil particles are almost invariably much smaller than those of their "reference" nonsoil counterparts with the same mineral names.

Soil clay minerals also differ from most, at least, of their nonsoil counterparts because of their associations with other species in soils. Apart from their ready association with organic matter that has already been discussed in this section, they are very commonly associated also with other minerals. Almost universally, they are associated with iron oxides (see Table 20.5 and Section 20.3.7) and, often, also with aluminum oxides. While the content of Fe in its various forms varies widely (Table 20.5), it is probably only in very young soils that it is nearly negligible in affecting soil properties. The youngest soil in a chronosequence on andesitic lava studied by Nieuwenhuyse et al. (2000) contained only 0.4% total Fe in its lowest, CB horizon. This horizon also contained 2.2% oxalate-extractable Al and, hence, ~8% allophane, but no phyllosilicate minerals (Nieuwenhuyse et al., 2000).

Table 20.5 also shows that soils are almost certainly never mono-mineralic in their secondary minerals. Only one of the soils shown there (an Orthoxic Tropohumult) is apparently monomineralic in phyllosilicates (kaolinite, in this case), but clearly also contains goethite, at least, in addition.

20.4.4 Nature of Soil Minerals and Relationship to Their Mode of Formation

Clearly, properties of soils relate to properties of clays besides those arising from their particular mineralogical characterization. Properties such as particle size and associations that minerals form with other minerals derive from their mode of formation. In general terms, minerals with a neogenetic origin from solutions in the soil occur in smaller particles than those formed by either transformation in the solid phase from primary minerals or even those that may be inherited from a source of minerals of authigenic origin from beyond the soil environment, for example, hydrothermally formed kaolinite and halloysite, or smectite in bentonite deposits of marine or lacustrine origins. A dramatic illustration of the differences that are wrought by pedogenesis in comparison with a nonsoil genesis (in this case, saprolitic) is given by the observation that the area of the 001 faces of kaolinite crystals that formed in the saprolite below 58 m depth in Brazil were more than five times larger than those that formed in the soil above it (Varajão et al., 2001). It is recalled that Kahle et al. (2002b) found that a combination of specific surface area and total (i.e., dithionite-extractable) Fe oxide content predicted C content almost completely in a set of illitic soils whereas explanations of C contents of other soils from mineral properties were more complex and usually involved poorly crystalline or nanocrystalline phases (see also Section 20.4.3). Even though the land-use history of the illitic soils and their pH may have played a role in simplifying the relationships between the inorganic (mineral) and organic components of the illitic soils (and, incidentally, in altering the course of mineral genesis), it is also most likely that the probable formation of the illite in the soils by transformation rather than neogenesis has led to mineral–organic relationships that are different from those in soils with higher proportions of neogenetic minerals, including poorly crystalline/nanocrystalline metal oxides (e.g., Kleber et al., 2005; Mikutta et al., 2005). Furthermore, it has been found that the nature of aggregation within soils dominated by kaolinites in close associations with Fe and Al oxides differs from that in soils that are more illitic. Both in a study in which aggregates were broken down mechanically (Oades and Waters, 1991) and another in which they were given the opportunity to build up through plant growth and inputs of plant residues (Denef and Six, 2005), aggregates in the kaolinitic soils were shown to comprise largely self-associations of minerals, while those in the illitic soils included close associations of minerals with organic matter.

The application of analytical techniques with higher resolution than XRD, and particularly electron microscopy, has shown that (1) "many clay particles in soils consist of complex inter-growths of different structural types rather than being the ideal monomineralic species described in textbooks" (Gilkes, 1990, p. 72); and (2) the extent and nature (e.g., charge) of two types of kaolinites (in different Australian soils) were quite different (op. cit., p. 67). Soils are highly heterogeneous in composition and are not simply mixtures of nonassociated entities. In particular, clay minerals are commonly coated by other minerals or organic matter, or both, so that the properties of their reactive surfaces reflect the characteristics of the coating material rather than the mineral substrate. For instance, it was found that "without exception, the suspended particles in rivers and gesturing waters were negatively and quite uniformly charged" (R.J. Hunter, 1981, in Mills, 2003, p. 11). It is almost certain that these particles had a soil source. Furthermore, "Since the particles themselves varied widely as to composition, Hunter concluded that this was likely due to a coating of organic matter or metal (iron, aluminum, and/or manganese) oxide" (Mills, 2003, p. 11).

These observations all suggest that the colloidal "particles" controlling soil properties are generally heterogeneous mixtures of various types of materials, both inorganic and organic. Predictions of their properties from those of well-crystallized minerals are likely to fall short of the mark. Grouping of soils by their dominant idealized mineral types can generally give only poor, or, at best, only qualitative, predictions of their properties. A structural alternative of grouping soils by the nature of their associations of, for example, particular aluminosilicate minerals, metal oxides, and organic matter together would provide the hopeless case of too many categories; indeed, each association would be very likely unique. A better alternative is suggested by the example of research into the nature of purely organic colloids in soils.

Organic colloids in soils are alternatively known as "humic macromolecules." Hayes et al. (1989, p. 16) have concluded, on theoretical grounds, that "it is highly unlikely that there are two humic macromolecules on earth … which are exactly the same." Even so, the field of the chemical and analytical study of organic colloids in soils is a very active one. It has had continuing success because instead of seeking definitive general structures of inevitably heterogeneous molecules, it has sought instead to characterize organic colloids by their "functional groups" (e.g., aromatic, carbohydrate, alkyl, carboxyl) —in other words, by their capacities to participate in reactions with other entities in soils.

Since a structural characterization of the "ultimate" particles or groupings of minerals would be similarly fraught with difficulties as that of organic colloids per se, it may be useful to classify soil minerals as contributors to soil properties (mostly via complex heterogeneous mixtures) through their characterization and appropriate grouping according to their most relevant capacities. These might include (on a weight basis) their surface area—as measured by various techniques, their charge and its variability with pH, their content of plant-available potassium, their shrink–swell capabilities, and their concentrations of reactive hydroxyl groups. Together, these properties reflect many of the most important for soil applications and may be correlated with other properties, for example, their affinity with organic matter and their capacity to adsorb phosphates or chlorides and other anions.

Nevertheless, selection of a set of useful properties by which to characterize mineral properties does not provide advances in understanding the origin of these properties. As has always been the case in mineralogical studies, this uncertainty will be reduced by advances in new instrumental techniques and in their application to soils. Undoubtedly, electron microscopy at higher resolutions, both for viewing and also for quantitative analyses, will be among these. Such techniques of surface analysis as XPS might also help. For example, Gerin et al. (2003) were able to analyze the nature of soil surface coatings, both of organic matter and also Fe and Al species, in order to better understand mineral-organic associations, and they projected more similar work with XPS. With the advent of synchrotron radiation, X-ray spectroscopic techniques, which include and enhance XPS and also XRD and XRF, but also encompass extended X-ray absorption fine structure (EXAFS), X-ray absorption near-edge structure (XANES), and other related methods have become available to determine the sites on mineral surfaces that are involved in interactions with other species (Gates, 2006).

Continuing developments in instrumental techniques undoubtedly enable better descriptions of processes involving minerals in soils, but the foregoing discussion nonetheless leads us to conclude that in order to be able to provide the best predictions or explanations of soil behavior from its clay mineralogy, the origins of the clays themselves must be thoroughly understood. The earlier parts of this chapter on the alteration, formation, and occurrence of minerals in soils thereby gains relevance to the understanding of soils both as useful materials and providers of essential ecological and human services.

Phyllosilicates

Hideomi Kodama
Agriculture and Agri-Food Canada

21.1 Introduction

Phyllosilicates, in other words, layer silicates, occupy one of six subclasses under the silicates class (Table 21.1). Phyllo- is after the Greek word describing the state of leaves, like a bed or heap of leaves. Thus in science, often the word is used as a prefix to express thin layer or paper sheet like in a book. This reflects general crystal habits and morphological features of the phyllosilicates. The silicates are abundant on the earth and of greater importance than any other minerals, which is easily understood from the fact that oxygen and silicon constitute nearly 75% of the elements in the earth's crust (Figure 21.1). The fundamental unit in all silicate structures is the silicon–oxygen tetrahedron (Figure 21.2). As Bragg (1950) stated, the bonds between silicon and oxygen are so strong that the four oxygen atoms are always found at the corners of a tetrahedron of nearly constant dimensions and regular shape whatever the rest of the structure may be like. The Si–O distance is about 0.16 nm, and the O–O distance 0.26 nm. Besides the crustal abundance of these two elements, the ionic radius of Si^{4+}, 0.042 nm, is conveniently accommodated in surroundings with four oxygens to form the fundamental structural unit of all silicates, the tetrahedron having the chemical formula $(SiO_4)^{4-}$. This unit can occur independently with compensating cations like Mg^{2+} and Fe^{2+}. And also these SiO_4 tetrahedra may be linked together by having one or more oxygen atoms shared in common by neighboring tetrahedra to form indefinitely extended and more complicated structural units to cover the existing silicate minerals. This mechanism of linking together is known as polymerization, and the classified structural units with their compositions are given in Table 21.2.

21.2 General Structural Features

The crystal structure of phyllosilicates has been determined largely by x-ray diffraction (XRD) methods that were well established within two to three decades of Roentgen's discovery of x-rays in 1895. The essential features of the mineral, typified by mica-like minerals, are the continuous 2D tetrahedral sheets of composition, $Si_2O_5^{2-}$, in which SiO_4 tetrahedra (Figure 21.3) are linked by sharing three corners of each tetrahedron to form a hexagonal mesh pattern (Figure 21.4a). Frequently Si atoms of the tetrahedra are partially substituted by Al and, to a lesser extent, by Fe^{3+}. The apical oxygen at the fourth corner of the tetrahedra, which is usually directed normal to the sheet, forms part of an adjacent octahedral sheet in which octahedra are linked by sharing edges (Figure 21.5). The junction plane between tetrahedral and octahedral sheets consists of the shared apical oxygens of the tetrahedra and unshared hydroxyls that lie at the center of each hexagonal ring of tetrahedra and at the same level as the shared apical oxygen atoms (Figure 21.6). Further details of octahedral configurations will be seen in Section 21.2.2, where the explanation of polytypes is given using the phlogopite structure as the example. Common cations that coordinate the octahedral sheets are Al, Mg, Fe^{3+}, and Fe^{2+}; but occasionally, Li, V, Cr, Mn, Ni, Cu, and Zn substitute in considerable amounts

TABLE 21.1   Six Subclasses under the Silicate Mineral Class

Subclass (Commonly Used)	Subclass (in Other Name)
Nesosilicates	Orthosilicates
Sorosilicates	Disilicates
Cyclosilicates	Ring silicates
Inosilicates	Chain silicates—Single chain and double chain
Phyllosilicates	Layer silicates
Tectosilicates	Framework silicates

into the sheets. If divalent cations (M^{2+}) are in the octahedral sheets, the composition is $M_3^{2+}(OH)_2O_4$ and all the octahedra are occupied; if trivalent cations (M^{3+}), the composition is $M_2^{3+}(OH)_2O_4$ and two-thirds of the octahedra are occupied, with the absence of the third octahedron. The former type of octahedral sheet is called trioctahedral (Figure 21.7a) and the latter dioctahedral (Figure 21.7b). This distinction may occasionally be used as a subgrouping for certain mineral groups

(e.g., mica). If all the anion groups are OH in the compositions of octahedral sheets, the resulting sheets may be expressed by $M^{2+}(OH)_2$ and $M^{3+}(OH)_3$, respectively. Such sheets called hydroxide sheets occur singly, alternating with silicate layers in some phyllosilicates, for example, in chlorite minerals. Brucite, $Mg(OH)_2$, and gibbsite, $Al(OH)_3$, are typical examples of minerals having similar structures.

There are two major types for structural "backbones" of phyllosilicates called silicate layers. The unit silicate layer formed by aligning one octahedral sheet to one tetrahedral sheet is referred to as a 1:1 silicate layer (Figure 21.8a), and the exposed surface of the octahedral sheet consists of hydroxyls. In another type, the unit silicate layer comprises one octahedral sheet sandwiched by two tetrahedral sheets, which are oriented in opposite directions and is termed a 2:1 silicate layer (Figure 21.8b). If hydroxide sheets in the chlorite structure are treated as a proxy for the octahedral sheet of the silicate layer and denoted as T for the tetrahedral sheet and O for the octahedral sheet, a majority of the phyllosilicates may be grouped by T–O type, T–O–T type, and T–O–T–O type, which correspond to 1:1, 2:1, and 2:2 (2:1:1 in some occasions) silicate layers, respectively.

Real structures of phyllosilicates, however, contain substantial crystal strains and distortions, which produce irregularities such as deformed octahedra and tetrahedra rather than polyhedra
FIGURE 21.8 Two basic silicate layer types of phyllosilicates: (a) 1:1 or T–O type silicate layer structure, (b) 2:1 or T–O–T type silicate layer structure. (With kind permission of Springer Science + Business media: Liebau, F. 1985. Structural chemistry of silicates: Structure, bonding, and classification. Springer-Verlag, New York.)

with equilateral hexagonal faces, ditrigonal symmetry modified from the ideal hexagonal surface symmetry, and puckered surface instead of the flat plane made up by the basal oxygen atoms of the tetrahedral sheet. One of the major causes of such distortions is dimensional "misfits" between the tetrahedral and octahedral sheets. If the tetrahedral sheet contains only silicon in the cationic site and has an ideal hexagonal symmetry, the longer unit dimension within the basal dimension is 0.915 nm, which lies between the corresponding dimensions 0.86 nm of gibbsite and 0.94 nm of brucite. To fit the tetrahedral sheet into the dimension of the octahedral sheet, alternate SiO_4 tetrahedra rotate (up to a theoretical maximum of 30°) in opposite directions to distort the ideal hexagonal array into a doubly triangular (ditrigonal) array (Figure 21.4b). By this distortion mechanism, tetrahedral and octahedral sheets of a wide range of composition due to ionic substitutions can link together and maintain silicate layers. Among ionic substitutions, those between ions of distinctly different sizes most significantly affect geometric configurations of silicate layers.

21.2.1 Ionic Sizes and Coordination Number

The arrangement of anions around a cation (as normally anions are larger than cations), defined as the coordination number, would be expected to be the most symmetrical in the three dimensions, that is, 3, 4, 6, 8, and 12 ions would be arranged at the apices of an equilateral triangle, regular tetrahedron, octahedron, cube, and closest packing in order to minimize its overall potential energy. Pauling (1929) first elucidated that most minerals follow the principles that are now commonly known as Pauling's first rule to distinguish from his second rule regarding structure stabilization by the sum of the electrostatic strengths between an anion and adjacent cations. Thus, as far as geometry is concerned, the ionic radius ratio, R_{cation}/R_{anion}, is the key factor for determining a polyhedron suitable for an arrangement of anions around a cation for a specific ionic combination. Assuming that ions act as rigid spheres of fixed radii, the stable arrangements of cations and

TABLE 21.3 Relationship between Radius Ratio ($R_{cation}/R_{O^{2-}}$) and Coordination Number

Radius Ratio (R_{cation}/R_{anion})	Arrangement of Anions around a Cation	Coordination Number of Cation	Crystal Models Shown in Figure 21.9
0.15–0.22	Corners of an equilateral triangle	3	a
0.22–0.41	Corners of a tetrahedron	4	b
0.41–0.73	Corners of an octahedron	6	c
0.73–1	Corners of a cube	8	d
1	Closest packing	12	e

anions for particular radius ratios can be calculated from purely geometric considerations (Table 21.3) and the corresponding 3D coordination models are shown in Figure 21.9. Anions in phyllosilicate structures are mostly oxygen ions, O^{2-}, with radius of 0.132 nm. Although to a lesser extent the structures may contain F^- and $(OH)^-$, radii of these anions are similar to that of oxygen. Therefore, for phyllosilicates, it is practical to compare the relationship of coordination number with the size of cation in terms of $R_{cation}/R_{O^{2-}}$ (Table 21.4). The table allows making prediction for the coordination number of a cation in phyllosilicates and for a possible ionic substitution at a specific structural site.

21.2.2 Polytypes

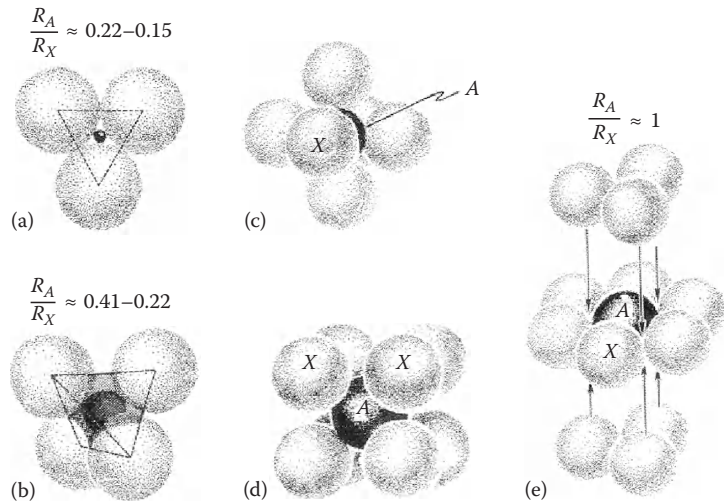
Because phyllosilicates maintain hexagonal or near-hexagonal symmetry, the structures allow various ways to stack up atomic planes, sheets, and layers, which may be explained by crystallographic operations such as translation or shifting and rotation, thereby distinguishing them from polymorphs (e.g., diamond–graphite; calcite–aragonite). The former involves 1D variations but the latter generally 3D ones. With a fixed chemical composition, structural varieties that are resulted from different stacking sequences are


FIGURE 21.9 Coordination number (ligancy) See Table 21.3 for further details of each crystal model. (Modified after Bloss, F.D. 1971. Crystallography and crystal chemistry. Holt, Rinehart and Winston, Inc., New York.)

TABLE 21.4 Radius of Cations Commonly Present in Phyllosilicates, Radius Ratio ($R_{cation}/R_{O^{2-}}$), and Predicted and Observed Coordination Numbers

Cation	Radius (nm)	$R_{cation}/R_{O^{2-}}$	Predicted Coordination Number	Observed Coordination Number

B^{3+}	0.023	0.17	3	3

termed polytypes. If such a variety is caused by ionic substitutions, which are minor but consistent, they are called polytypoids.

To understand this specific feature of phyllosilicates, consider the magnesium mica, phlogopite, as an example. Its silicate layer in terms of a sequence of atom planes is given in Figure 21.10. In the figure, T_L represents the atom plane at the level of apical oxygen atoms (●, solid circles) of the lower tetrahedral sheet and at the same level and hydroxyl (double circles with O and ●) fills the center of a hexagonal array made up by six apical oxygen atoms. In addition, the projection to the plane of basal oxygen atoms (○, open circles) of the tetrahedral sheet is also included. O_T is the octahedral cation plane where magnesium atoms are represented by small solid circles (●). T_U corresponds to the atom plane of the upper tetrahedral sheet. Unlike T_L, the direction of apical oxygen atoms is opposite to that of T_L. In T_U, the apical oxygen atoms, hydroxyls, and the projections of the basal oxygen atoms are expressed by an open circle with shaded circle, double circles, and solid circles, respectively. The lower tetrahedral sheet and the upper tetrahedral sheet having opposing vertices to each other are held together by magnesium ions. Each magnesium ion is linked to two oxygen anions and one hydroxyl from the lower tetrahedral sheet and two oxygen anions and one hydroxyl from the upper sheet to make a six coordination packing. This packing mechanism requires that the upper tetrahedral sheet be staggered by $-a/3$, where a is the unit cell dimension along the a-axis, relative to the lower tetrahedral sheet. The staggering between the two sheets, therefore, gives a monoclinic nature to the silicate layer, and this nature is common to all the basic silicate layers of phyllosilicates. The interlayer atom plane is denoted as I, in which solid circles represent potassium atoms. At the interlayer position, for example, between two silicate layers, each interlayer potassium ion keys the two layers without shift by coordinating 12 basal oxygens, 6 each from lower and upper tetrahedral sheets. Although due to the presence of interlayer potassium ions there is no shift between the two silicate layers, the orientation of the upper one
FIGURE 21.10 Idealized sketches of mica structure (phlogopite) and its structural segments (atomic planes) at four levels. (After Kodama, H. 1990. Use of color-coded transparencies for visualizing layer silicate structures, p. 169–175. *In* V.C. Farmer and Y. Tardy (eds.) Proc. 9th Int. Clay Conf. 1989. Strasbourg. Sci. Géol., Mém. Strasbourg, France.)

can be changed with respect to the lower one. Because these basal oxygen planes have a hexagonal or a pseudohexagonal symmetry, there are six or three possible orientations, which are related by $n \times 60°$ rotations, at maximum six angles: 0°, 60°, 120°, 180°, 240°, and 300°. Among them, angles 60° and 300° are equivalent, as also are angles 120° and 240°, because the silicate layer itself has the plane of symmetry, which is parallel to the layer stagger. Thus, 0°, 60°, 120°, and 180° rotation operations lead theoretically to six simple- ordered-stacking mica layers, and they were depicted by vectors from one potassium atom to a potassium atom in the next layer in the direction of increasing height of the mica layers (Smith and Yoder, 1956). Resulting layer structures having different layer-stacking sequences are called polytypes. Mica polytypes derived by them are $1M$ (0° rotation), $2M_1$ (a continuous alternation of ±120° rotation), $2M_2$ (a continuous alternation of ±60° rotation), $3T$ (±120° rotation), $2Or$ (±180° rotation), and $6H$ (±60° rotation), as expressed in an adapted simple nomenclature. The first symbol gives the number of layers in the repeat unit (subcell) and the second in italics gives the symmetry. In case of the same symmetry, the subscripts 1 and 2 are used for further distinction. Therefore, $1M$, $2M$, $3T$, $2Or$, and $6H$ indicate one-layer monoclinic, two-layer monoclinic, three-layer trigonal, two-layer orthorhombic, and six-layer hexagonal, respectively. Similar consideration can be applied to other types of layer silicates such as T–O and T–O–T–O. If polytypes are reported in nature, in the glossary of phyllosilicates given at the end of this chapter (compiled from Blackburn and Dennen, 1997, and Lalonde, 2003) a specific mineral name is given, for example, Phlogopite-$1M$, Kaolinite-$1Tc$, where the letter Tc represents triclinic. The descriptions stated above are based on the ideal or nearly ideal structure. In practice, however, there are many factors that affect the formation of polytypes, that is, ionic substitutions in the octahedral sheets, ionic substitutions for silicon atoms in the tetrahedral sheets, the degree of ordering of these substitutions, the vacancy distributions in the octahedral sheets, which normally exist in the dioctahedral layer silicates or may be caused by the oxidation of Fe^{2+} to Fe^{3+} in the sheets. These variations add more complexities to the form of polytypes.

21.2.3 1:1 Layer Type (T–O Type)

21.2.3.1 General

The structure of this type is shown in Figure 21.6 (also Figure 21.8), which was used for explaining the junction between tetrahedral and octahedral sheets. A 2D tetrahedral sheet, made up by sharing three corners of each SiO_4 tetrahedron, are attached to an octahedral sheet, thereby each cation in the octahedral sheet associates with two apical oxygen atoms and four hydroxyls to make up six coordination binding. Thus, the structure of this type of layer silicate consists of tetrahedral and octahedral sheets in which the anions at the exposed surface of the octahedral sheet are hydroxyls. General structural formula may be expressed by $Y_{2-3}Si_2O_5(OH)_4$, where Y are cations in the octahedral sheet such as Al^{3+} or Fe^{3+} for dioctahedral species and Mg^{2+}, Fe^{2+}, Mn^{2+}, or Ni^{2+} for trioctahedral species.

21.2.3.2 Serpentine–Kaolin Group

This group contains two subgroups, trioctahedral and dioctahedral. Serpentine minerals with the ideal formula of
FIGURE 21.11 Electron micrograph of chrysotile. Most of the fibrils appear "solid," but a few show the appearance of hollow tubes, and a few show "open ends." (From Gard, J.A. (ed.). 1971. The electron-optical investigation of clays. Monograph No 3. Mineralogical Society, London, U.K. Reproduced with permission of The Mineralogical Society of Great Britain and Ireland.)

$Mg_3Si_2O_5(OH)_4$ represent the former, and kaolin minerals with $Al_2Si_2O_5(OH)_4$ represent the latter. Among trioctahedral magnesium species, chrysotile, antigorite, and lizardite are commonly known and their morphology and structure are uniquely different. (Wicks and Whittaker, 1975; Wicks and Zussman, 1975) Electron microscopic observations show that chrysotile crystals have a fibril appearance (Figure 21.11), but its cross sections clearly show cylindrical roll morphology (Figure 21.12a and b); whereas, antigorite crystals exhibit lath-shape morphology (Figure 21.13a), but the electron-diffraction photograph indicates an alternating wave structure as shown by the presence of segmental groups of superlattice spots (Figure 21.13b). The structure deduced by Kunze (1956) consists of curved layers elongated along the a-axis, but the layers change alternately their polarity (or the direction of apical oxygens in the tetrahedral sheets) at half a period of the wave to make up a full periodicity of 4.35 nm, which is the dimension of a of antigorite (Figure 21.14). These alternating wave structural characteristics may be attributed to the degree of fit between the lateral dimensions of the tetrahedral and octahedral sheets. On the other hand, lizardite crystals are platy (Figure 21.15) and have often a small amount of substitution of Al or Fe^{3+} for both Si and Mg. This substitution appears to be the main reason for the platy nature of lizardite. Obviously, morphology is one of the key characteristics to distinguish among serpentine minerals. A few selected chemical compositions of serpentine minerals are given in Table 21.5 for reference. Other than Mg, Fe^{2+}, Ni, and Mn can occupy the octahedral sites and form species such as berthierine, brindleyite, and kellyite. Chemical compositions of some such varieties are given in Table 21.6. Planar polytypes of the trioctahedral species are far more complicated than those of the dioctahedral ones, owing to the fact that the trioctahedral silicate layer has a higher symmetry because all octahedral cationic sites are occupied. Polytype structures, such as one-layer trigonal ($1T$), one-layer monoclinic ($1M$), two-layer hexagonal ($2H_1$, $2H_2$), two-layer trigonal ($2T$), two-layer orthorhombic ($2Or$), two-layer monoclinic ($2M_1$, $2M_2$), three-layer rhombohedral ($3R$),

1, Hydrated halloysite (halloysite—1 nm), Wagon Wheel Gap, Colorado (Larsen and Wherry, 1917); 2, halloysite (halloysite—0.7 nm), Djebel Debar, Morocco (Garrett and Walker, 1959); 3, iron-rich hydrated halloysite, Hokkaido, Japan (Wada and Mizota, 1982).

See Newman (1987) for original data.

three-layer trigonal (3T), six-layer hexagonal (6H), and six-layer rhombohedral (6R) are reported (Bailey, 1969, 1980, 1988).

For the dioctahedral subgroup, kaolin minerals include kaolinite (one-layer triclinic, 1Tc), dickite (two-layer monoclinic, 2M), and nacrite (two-layer monoclinic, 2M), which are in polytypic relation. Examples of the chemical composition of kaolin minerals are given in Table 21.7. Kaolinite has triclinic symmetry. Oxygen atoms and hydroxyl ions between the layers are paired with hydrogen bonding. Because of this weak bonding, random displacements between the layers are quite common and result in a poor symmetry rather than distinctive triclinic kaolinite. Dickite and nacrite are polytypic varieties of kaolinite. Both of them consist of a double 1:1 layer and have monoclinic symmetry but distinguish themselves by different stacking sequences of the two 1:1 silicate layers.

21.2.3.3 Halloysite—Hydrated Halloysite Group

Halloysite has a composition close to that of kaolinite (Table 21.8) and is characterized by its tubular nature (see Figure 21.27) in contrast to the platy nature of kaolinite particles. Although tubular forms are the most common, other morphological varieties are also known: prismatic, rolled, pseudospherical (Figure 21.16), and platy forms. The structure of halloysite is believed to be

FIGURE 21.16 Electron micrograph of halloysite (with spherical structure), altered from glassy tuff. (From Sudo, T. 1959. *Mineralogical study on clays of Japan*. Maruzen Co. Ltd., Tokyo, Japan.)

similar to that of kaolinite, but no precise structure has been revealed yet. Halloysite has a hydrated form with composition of $Al_2Si_2O_5(OH)_4 \cdot 2H_2O$. This hydrated form irreversibly changes to a dehydrated variety at relatively low temperatures (60°C) or upon being exposed to conditions of low relative humidity. The dehydrated form has a basal spacing about the thickness of a kaolinite layer (approximately 0.72 nm), and the hydrated form has a basal spacing of about 1.01 nm, the difference of 0.29 nm is approximately the thickness of one molecular layer of water. Consequently, in the hydrated form of halloysite, its silicate layers are separated by monomolecular water layers that are lost during dehydration.

21.2.4 2:1 Layer Type (T–O–T Type)

21.2.4.1 General

As seen in Figure 21.8b, the unit silicate layer of T–O–T type comprises one octahedral sheet sandwiched by two tetrahedral sheets, which are oriented in opposite directions and may be termed a 2:1 layer type. A majority of phyllosilicates hold a backbone of this type for their structures. This type includes talc, pyrophyllite, micas, brittle micas, vermiculite, and smectite.

21.2.4.2 Talc–Pyrophyllite Group

Minerals of this group have the simplest form of 2:1 layer with its unit thickness of approximately 0.92–0.96 nm—that is, the structure consists of an octahedral sheet sandwiched by two tetrahedral sheets. Talc and pyrophyllite represent the trioctahedral and dioctahedral members, respectively, of the group. In the ideal case, the structural formula of talc is expressed by $Mg_3Si_4O_{10}(OH)_2$ and pyrophyllite by $Al_2Si_4O_{10}(OH)_2$. Selected analyses are given in Table 21.9. Figure 21.17 shows these two structures as an extended crystal model, where the staggering between tetrahedral sheets above and below and the difference in octahedral sheets between talc and pyrophyllite is clearly seen. Each 2:1 layer of these minerals is electrostatically neutral; therefore, van der Waals forces hold the silicate layers together. One-layer triclinic and two-layer monoclinic forms are known for polytypes of pyrophyllite and talc. The ferric iron analog of pyrophyllite is called ferripyrophyllite.

21.2.4.3 True Mica Group

Mica has a basic structural unit of 2:1 layer type, like pyrophyllite or talc, but some of the silicon atoms (ideally one-fourth) are always replaced by aluminum atoms. This results in a charge deficiency that is balanced by potassium ions between the unit layers (Figure 21.18). The sheet thickness (basal spacing or dimension along the direction normal to the basal plane) is fixed at about 1 nm. Typical examples are muscovite, $KAl_2(Si_3Al)O_{10}(OH)_2$ for dioctahedral species and phlogopite, $KMg_3(Si_3Al)O_{10}(OH)_2$, and biotite, $K(Mg,Fe)_3(Si_3Al)O_{10}(OH)_2$, for trioctahedral species. Formulas rendered may vary slightly due to possible substitution within certain structural sites. The interlayer cation can be sodium instead of potassium, notably paragonite

Analysis 2 is referred from Deer et al. (1962). Analyses 3, 4, and 5 are taken from Newman (1987). See Newman (1987) for original source of each analysis except analyses 1 and 2.

in this case, which has an ideal formula of $NaAl_2(Si_3Al)O_{10}(OH)_2$. Various polytypes of the micas are known to occur. Among them one-layer monoclinic ($1M$), two-layer monoclinic ($2M$ including $2M_1$ and $2M_2$), and three-layer trigonal ($3T$) polytypes are the most common. The majority of clay-size micas are dioctahedral aluminous species; those similar to muscovite are called illite (Bailey et al., 1984). The illites are different from muscovite in that the amount of substitution of aluminum for silicon is less, sometimes only one-sixth of the silicon ions are replaced. This reduces a net unbalanced charge deficiency from 1 to about 0.65 per chemical formula unit. As a result, the illites have a higher silica-to-alumina molecular ratio and lower potassium content than the muscovites (Graf von Reichenbach and Rich, 1975; Fanning et al., 1989). To some extent, octahedral aluminum ions are replaced by magnesium (Mg^{2+}) and iron ions (Fe^{2+}, Fe^{3+}). In the illites, stacking disorders of the layers are common, but their polytypes are often unidentifiable. Celadonite and glauconite are ferric ion-rich species of dioctahedral micas. The ideal

composition of celadonite may be expressed by $K(Mg,Fe^{3+})$ $(Si_{4-x}Al_x)O_{10}(OH)_2$, where $x = 0–0.2$. Glauconite is a dioctahedral mica species with tetrahedral Al substitution greater than 0.2 and octahedral Fe^{3+} or R^{3+} (total trivalent cations) greater than 1.2. Unlike illite, a layer charge deficiency of celadonite and glauconite arises largely from the unbalanced charge due to ionic substitution in the octahedral sheets. Some chemical analyses of dioctahedral micas (Tables 21.10 and 21.11) and of trioctahedral

micas (Table 21.12) are given for reference. Comprehensive reviews on true micas are available (Bailey, 1984; Fleet, 2003).

21.2.4.4 Brittle Mica Group

Brittle micas are distinguished from true micas in having a layer charge of ~2.0 per formula unit, which arises entirely within the tetrahedral sheet or partly within the tetrahedral sheet and partly octahedral sheet. The tetrahedral composition varies

from SiAl$_3$ to nearly Si$_3$Al and this is supplemented by octahedral sheet charges that range from +1.0 to 0 to nearly −1.0. As the layer charge is higher than that of true micas, divalent interlayer cations are required for compensation, instead of monovalent.

Clintonite is a trioctahedral species of ideal composition, Ca(Mg$_2$Al)(SiAl$_3$)O$_{10}$(OH)$_2$. Because high Al content in the tetrahedral sheet and Al atomic radius size is larger than Si, the hexagonal symmetry of the tetrahedral sheet is modified to ditrigonal (Figure 21.4b) by a tetrahedral rotation of 23° to match the lateral dimensions of the octahedral sheet. The reported polytypes are 1*M*, 2*M*$_1$, and 3*T*. Margarite is a known sole dioctahedral species in the brittle mica group, having ideal composition CaAl$_2$(Si$_2$Al$_2$)O$_{10}$(OH)$_2$, and with a 2*M*$_1$ structure. Other species belonging to the group include kinoshitalite (1*M* and 2*M*$_1$), with ideal formula BaMg$_3$(Si$_2$Al$_2$)O$_{10}$(OH)$_2$; anandite (2*Or*), with Ba(Fe,Mg)$_3$(Si$_3$Fe^{3+})O$_{10}$(OH)S; and bityite (2*M*$_1$), with BaLiAl$_2$(Si$_2$AlBe)O$_{10}$(OH)$_2$. Polytypes in brackets are only of high abundance. Analyses of representative brittle micas are given in Table 21.13.

21.2.4.5 Vermiculite Group

The vermiculite unit structure consists of talc-like 2:1 silicate layers separated by two molecular layers of water (approximately 0.48 nm thick). Substitutions of aluminum (Al^{3+}) for silicon (Si^{4+}) in tetrahedral sheets constitute the chief charge imbalance, but the net-charge deficiency may be partially balanced by other substitutions within the 2:1 silicate layer; but a residual net-charge deficiency always exists, commonly in the range 0.6–0.8 per O$_{10}$(OH)$_2$. This charge deficiency is satisfied with interlayer cations, which are closely associated with the water molecules between the silicate layers (Figure 21.19); Mathieson and Walker, 1954. As the net-charge deficiency is higher than smectites, in vermiculites interlayer water molecules are better coordinated with interlayer cations. In macroscopic vermiculites of hydrothermal origin, unlike those in soils, the balancing cation is mostly magnesium (Mg^{2+}), sometimes associated with a small amount of calcium (Ca^{2+}). The interlayer cation, however, is readily replaced by other inorganic and organic cations. A number of water molecules are related to the hydration state of cations located at the interlayer sites. Therefore, the basal spacing of vermiculite changes from about 1.05 to 1.57 nm, depending upon its crystal size, relative humidity, and the kind of interlayer cation. If potassium or ammonium ions are not present in the interlayer sites, in some extreme cases, heating vermiculite to temperatures as high as 500°C drives the water out from between the silicate layers, but the mineral quickly rehydrates at room temperature to maintain its normal basal spacing of approximately 1.4–1.5 nm. Special care would, therefore, be required to examine the dehydration–rehydration temperature of a vermiculite mineral in question.

If complete and irreversible dehydration occurs, the basal spacing becomes 0.902 nm. Figure 21.20 illustrates various hydration states of vermiculite. Note, however, that these states are affected by crystal size of the sample. Some dioctahedral analogs of vermiculite have also been reported to occur in soils (Brown, 1953).

21.2.4.6 Smectite Group

The structural units of smectite (Figure 21.21) can be derived from the structures of pyrophyllite and talc. Unlike pyrophyllite and talc, the 2:1 silicate layers of smectite have a slight negative charge owing to ionic substitutions in the octahedral and tetrahedral sheets. The net-charge deficiency is normally smaller than that of vermiculite from ~0.2 to 0.6 per $O_{10}(OH)_2$ and balanced by the interlayer cations as in vermiculite (Table 21.14). This weak bond offers an excellent cleavage between the layers. The distinguishing feature of the smectite structure from the other types is that water and other

polar molecules (in the form of certain organic substances) can, by entering between the unit layers, cause the structure to expand in the direction normal to the basal plane. Thus, this dimension may vary from about 0.96 nm, when no polar molecules are between the unit layers, to nearly complete separation of the individual layers.

The structural formula of dioctahedral aluminous smectites may be represented by $M_{x+y}^+ (Al_{2-y}Mg_y^{2+})(Si_{4-x}Al_x)O_{10}$ $(OH)_2 \cdot nH_2O$, with $0.2 \leq x + y \leq 0.6$, where M^+ is the interlayer exchangeable cation expressed as a monovalent cation and x and y are the amounts of tetrahedral and octahedral substitutions, respectively. The smectites with $y > x$ are called montmorillonite and those with $x > y$ are known as beidellite. In the latter type of smectites, those in which ferric iron is a dominant cation in the octahedral sheet instead of aluminum and magnesium are called

nontronite or ferruginous smectite. Although less frequent, chromium (Cr^{3+}) and vanadium (V^{3+}) also are found as dominant cations in the octahedral sheets of the beidellite structure; in the case of chromium, the mineral is named volkonskoite.

The ideal structural formula of trioctahedral ferromagnesian smectites, the series saponite through iron-saponite, is given by $M_x^+(Mg,Fe^{2+})_3(Si_{4-x}Al_x)O_{10}(OH)_2 \cdot nH_2O$. Tetrahedral substitution is responsible for the net-charge deficiency in the smectite minerals of this series. Besides magnesium and ferrous iron, zinc, cobalt, and manganese are known to be dominant cations in the octahedral sheet. Zinc-dominant species are called sauconite. In other types of trioctahedral smectites, the net-charge deficiency arises largely from ionic substitution or a small number of cation vacancies in the octahedral sheets, or from both. Ideally *x* is 0, but most often it is less than 0.15. Thus, the octahedral composition varies to maintain

similar amounts of net-charge deficiency as those of other smectites. Typical examples are $(Mg_{3-y}\square_y)$ for stevensite and $(Mg_{3-y}Li_y)$ for hectorite, respectively, where $\square$ denotes a vacancy site in the structure. In stevensite, therefore, *y* sites out of three are vacant.

The structure of smectites described above is based on their ideal model. Their actual structures are more or less distorted and show different physical appearances due to various circumstances. Electron optical diffraction examinations are most effective for their characterization. According to the accounts of Méring and his colleagues (Méring and Brindley, 1967; Méring and Oberlin, 1967, 1971; Méring, 1975), three types of layer-stacking arrangement have been observed and classified. Particles of smectites are composed of a stacking of elementary layers, in which on the average 10–20 elementary layers are stacked together, and their arrangements are ordered, semiordered, or turbostratic.

The ordered arrangement should give a clear hexagonal net (spots) pattern by the electron microdiffraction diagram. In semiordered arrangement, the mutual orientation of the elementary layers is defined by arbitrary multiples of 60°. Therefore, the stacking is no longer a triperiodic crystal but maintains "hexagonal" symmetry. If disorientation is defined by rotations about the c^*-axis (normal to the basal plane of smectites), layer stacking is called turbostratic. With the disorientation, diffraction spots of hk become diffuse and elongated, and the extent of those effects are related to the degree of disorientation. Turbostratic arrangements are unique to smectite minerals and no other phyllosilicates with such structure are known. Typically montmorillonite, hectorite, and nontronite show turbostratic structure. Beidellite and saponite are, on the other hand, known to possess relatively ordered structures.

21.2.5 2:1:1 Layer Type (T–O–T–O Type)

21.2.5.1 Chlorite Group

The structure of the chlorite minerals consists of alternate mica-like layers and brucite-like hydroxide sheets about 1.4 nm thick (Figure 21.22). Structural formulas of most trioctahedral chlorites may be expressed by four end-member compositions:

$$(Mg_5Al)(Si_3Al)O_{10}(OH)_8 \quad \text{(clinochlore)}$$
FIGURE 21.22 The structure of chlorite. (From Grim, R.E. 1968. Clay mineralogy. McGraw-Hill Book Co. Inc., New York. With permission.)

$$(Fe_5^{2+}Al)(Si_3Al)O_{10}(OH)_8 \quad \text{(chamosite)}$$

$$(Mn_5Al)(Si_3Al)O_{10}(OH)_8 \quad \text{(pennantite)}$$

$$(Ni_5Al)(Si_3Al)O_{10}(OH)_8 \quad \text{(nimite)}$$
The unbalanced charge of the silicate layer is compensated by an excess charge on the hydroxide sheet caused by the substitution of trivalent cations (Al^{3+}, Fe^{3+}, etc.) for divalent cations (Mg^{2+}, Fe^{2+}, etc.). Chlorites, with an aluminous dioctahedral silicate layer and an aluminum hydroxide sheet are called donbassite and have the ideal formula of $Al_{4.33}(Si_3Al)O_{10}(OH)_8$ as an end-member for the dioctahedral chlorite. However, in many cases, the octahedral Al ions are partially replaced by magnesium, as in magnesium-rich aluminum dioctahedral chlorites, which are called sudoite. Cookeite is another type of dioctahedral chlorite, in which lithium (Li) substitutes for aluminum in the octahedral sheets. Selected chemical analyses are listed in Table 21.15. The symmetry of chlorite structures is variable due to the kind and amount of substitutions within the hydroxide sheet and within the tetrahedral and octahedral sites of the 2:1 silicate layer, the orientation of successive octahedral and tetrahedral sheets, and the way of the stacking of successive chlorite units. Specifically, as the chlorite unit contains hydroxide layers, the way of stacking between the basal oxygen atoms of the tetrahedral sheet and the hydroxyls in the first atomic plane of the hydroxide sheet is unique for chlorite. According to Shirozu and Bailey (1965), among six possible polytypes four are known to naturally occur and they are denoted as Ia, Ib ($\beta = 97°$), Ib ($\beta = 90°$), and IIb, respectively. Type I and Type II are distinguished by a difference in the shifting direction of the silicate layer with respect to that of the successive hydroxide sheet. Designation a indicates the case in which two-thirds of cations in the hydroxide sheet locate above tetrahedral cations and the remaining octahedral cations occupy at the center of the hexagonal rings, whereas designation b is the case in which cations of the hydroxide sheet distribute symmetrically upon projecting them onto the hexagonal ring. An overwhelmingly common polytype in nature is the single-layer monoclinic structure designated as IIb. A majority of trioctahedral chlorites including sudoite takes this polytype, while Ib ($\beta = 97°$) and Ib ($\beta = 90°$) polytypes are abundant in iron-rich chlorites. The Ia polytype is often realized in cookeite and donbassite. Chlorite structures are relatively thermally stable compared to kaolinite, vermiculite, and smectite minerals. Due to this, the presence of the XRD peak at 1.4 nm after heat treatment at 500°C–700°C is widely used for the identification of chlorite minerals.

21.2.6 Interstratified Layer Silicate Group (Mixed-Layer Type)

As seen from the foregoing discussion, structures of phyllosilicates are strikingly similar except for sheet sequence such as T–O and T–O–T and layer thickness. Because of similarity as such, nature finds that a layer silicate of one kind interstratifies with that of another kind to make up a new structure that differs from either component layer.

Analyses 1–4 and 8 are taken from Anthony et al. (1995). Analyses 5–7 are taken from Newman (1987) and modified to fit with the table. For original data source, see Anthony et al. (1995) or Newman (1987).

The most striking examples of interstratified structures are those having a regular *AB AB* … type structure, where *A* and *B* represent two different component layers. The interstratified minerals of this type show a long periodicity along the *c**-axis (normal to the basal plane) of the structure, which is the sum of the two individual periodicities of the component layers *A* and *B*. Several minerals are known to have structures of this type, that is, rectorite (dioctahedral mica/montmorillonite), tosudite (dioctahedral chlorite/smectite), corrensite (trioctahedral vermiculite/chlorite) in two types with high- and low-layer charge vermiculite,

hydrobiotite (trioctahedral mica/vermiculite), aliettite (talc/saponite), and kulkeite (talc/chlorite). Analyses of selected samples of those regular interstratifications are shown in Table 21.16.

Other than the *AB AB* … type with equal numbers of the two-component layers in a structure, a variety of modes of the layer-stacking sequence is possible from nearly regular to completely random. The following interstratifications of two components are reported in these modes in addition to those given above: Illite–smectite, glauconite–smectite, dioctahedral mica–chlorite, dioctahedral mica–vermiculite, and kaolinite–smectite. As the mixing

ratio (proportion of the component layers) of the two-component layers varies, the number of possible layer-stacking modes increases greatly. Theoretically, any number of the kinds of component layers can form interstratified structures. In practice, however, a maximum of three-component layers have been positively identified. Interstratified structures consisting of illite–chlorite–smectite and illite–vermiculite–smectite have been reported so far. Because certain interstratified structures are known to be stable under relatively limited conditions, their occurrence may be used as a geothermometer or other geoindicator. On the other hand, Nadeau (1985) and Nadeau et al. (1984a, 1984b) proposed the fundamental particle theory, which argues that interstratified structures may be considered as artifacts of sample preparation. Extra caution is required to describe interstratified layer silicates correctly.

21.2.7 Modulated Layer Silicate Group

21.2.7.1 General

Guggenheim and Eggleton (1988) defined modulated layer silicates as those minerals that contain a periodic perturbation to the basic layer silicate structure. The basic structure involves 1:1 or 2:1 layer configurations. Thus, as the severity of the modulations increases, 2D continuous layer-like qualities diminish. The octahedral sheet of a modulated layer silicate is invariably a brucite-like (trioctahedral) sheet. Palygorskite, sepiolite, greenalite, minnesotaite, caryopilite, zussmanite, stilpnomelane, ganophyllite, bementite, etc. are known to be mineral species belonging to this group. Strictly speaking, antigorite may also be treated as one of the modulated 1:1 layer silicates. In this chapter the "phyllosilicate" antigorite is thought to be represented in comparison with its other counterparts.

21.2.7.2 Sepiolite–Palygorskite Group

Sepiolite and palygorskite are papyraceous or fibrous hydrated magnesium silicate minerals (Figure 21.23) and are included in

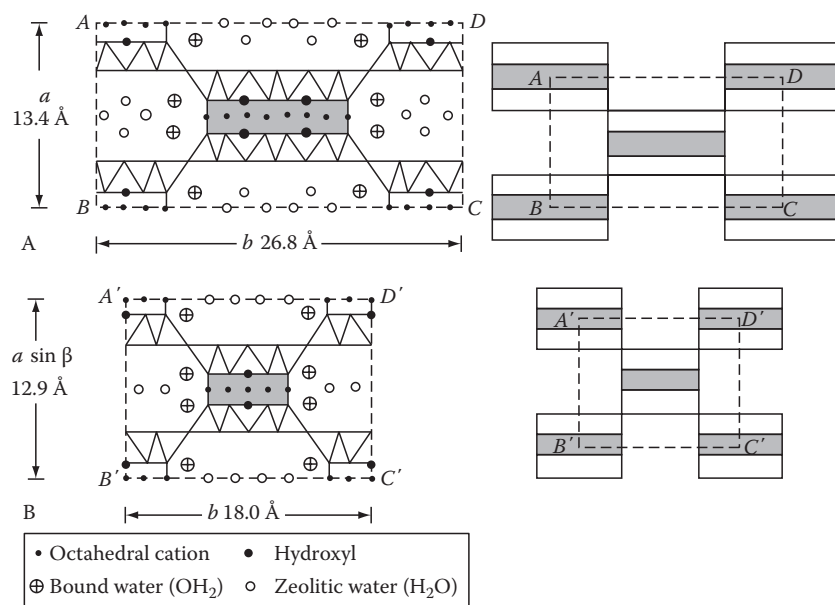
FIGURE 21.23 Electron micrograph of palygorskite from Nawton, near Thirsk, Yorkshire. (From Gard, J.A. (ed.). 1971. The electron-optical investigation of clays. Monograph No 3. Mineralogical Society, London, U.K. Reproduced with kind permission of The Mineralogical Society of Great Britain and Ireland.)


FIGURE 21.24 Structural sketches of palygorskite and sepiolite. (Reprinted from Sudo, T., S. Shimoda, H. Yotsumoto, and S. Aita. 1981. Electron micrographs of clay minerals. Developments in sedimentology. Vol. 31. Elsevier Scientific Publishing Co., New York. With permission from Elsevier.)

the phyllosilicates because they contain a continuous 2D tetrahedral sheet of composition Si_2O_5. They differ, however, from the other layer silicates because they lack continuous octahedral sheets. The structures of sepiolite and palygorskite are alike and can be regarded as consisting of narrow strips or ribbons of 2:1 layers that are linked stepwise at the corners (Figure 21.24). One ribbon is linked to the next by inversion of the direction of the apical oxygens of SiO_4 tetrahedra, in other words, an elongated rectangular box consisting of a continuous 2:1 layer is attached by the nearest boxes at their elongated corner edges. Therefore, channels or tunnels due to the absence of the silicate layers occur on the elongated sides of the boxes. The elongation of the structural element is related to the fibrous morphology of the minerals and parallel to the *a*-axis. Since the octahedral sheet is discontinuous, some octahedral magnesium ions are exposed at the edges and hold bound water molecules (OH_2). In addition to the bound water, variable amounts of zeolitic (i.e., free) water (H_2O) are contained in the rectangular channels. The major difference between the structures of sepiolite and palygorskite is the width of the ribbons, which is greater in sepiolite than in palygorskite. The width determines the number of octahedral cation positions per formula unit. Thus, sepiolite and palygorskite have the ideal compositions $Mg_8Si_{12}O_{30}(OH)_4(OH_2)_4(H_2O)_8$ and $(Mg,Al,\square)_5Si_8O_{20}(OH)_2(OH_2)_4(H_2O)_4$, respectively. Some of Mg in sepiolite may be replaced by Al, Fe^{3+}, or Fe^{2+}. Selected analyses of this mineral group are given in Table 21.17.

21.2.7.3 Greenalite, Minnesotaite, and Caryopilite

Greenalite was once expected to be a near iron end-member of serpentine. Guggenheim et al. (1982) showed that its structure is composed of coherent intergrowths of a trigonal polytype and a monoclinic polytype, with volume wise the former being larger than the latter and having a domain size of about 2 nm. Minnesotaite has a continuous octahedral sheet (Guggenheim and Bailey, 1982). Adjacent tetrahedral are present on either side of this sheet to form an approximate 2:1 layer. However, in contrast to talc, strips of linked hexagonal rings of tetrahedra are formed only parallel to *y* (Figure 21.25; Guggenheim and Eggleton, 1986). Some analyses of greenalite and minnesotaite are listed in Table 21.18, in which an analysis of caryopilite, as a mangan species of serpentine-like mineral, is included for comparison.

21.3 Occurrence of Phyllosilicates

21.3.1 As Rock-Forming Minerals

Known established species of phyllosilicates are no more than 100 (see Appendix). Although this is a rather small portion of the total mineral kingdom of some 3700 species, the occurrence of phyllosilicates is spread to a wide variety of geological environments. Among those described in the previous sections, perhaps biotite is the most; it is found in igneous rocks varying from granitic pegmatites, to granites, to syenites, to diorites, and to gabbros and peridotites. It also occurs in felsic volcanic rocks such as dacites, rhyolites, trachyte, and phonolites. In metamorphic rocks, including contact-metamorphosed rocks, biotite is formed under a wide range of temperature and pressure conditions. Muscovite is also a widespread and common rock-forming mineral, especially in pegmatites and granitic rocks. It is often found in metamorphic rocks as mica schists and as green schists with chlorite. Phlogopite occurs in metamorphosed magnesium limestones, dolomites, and ultrabasic rocks. Lepidolite is an uncommon mineral, found in lithium-rich pegmatites. Some brittle micas occur in regional contact-metamorphosed rocks.

21.3.2 Hydrothermal Origin and the Term "Clay Minerals"

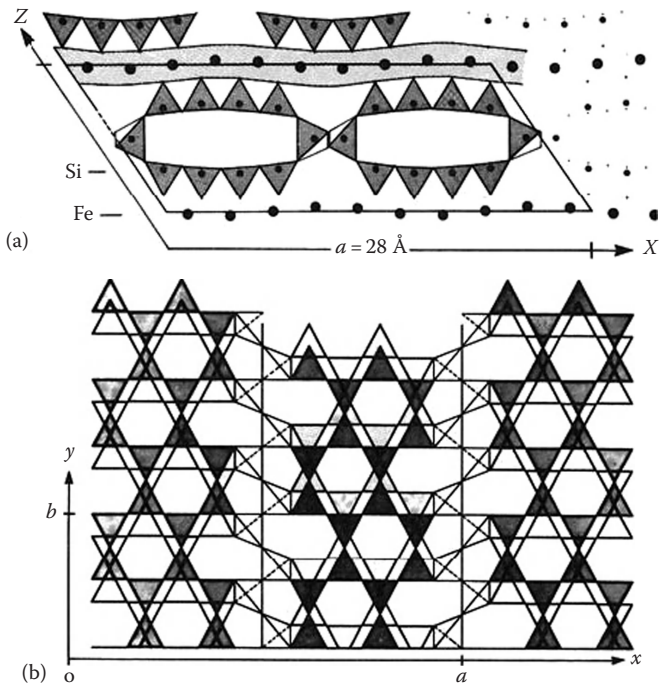
In hydrothermal deposits or wall-rock alteration zones, many of phyllosilicates except palygorskite and sepiolite have been found as alteration products associated with hot springs and geysers and as aureoles around metalliferous deposits. Frequently a zonal arrangement of phyllosilicates, normally as very fine-grained clayey materials, is observed around the source of the alteration. The zonal arrangement varies with the type of parent rocks and the nature of hydrothermal solution. Extensive clay zones formed in close association with "kuroko" deposits contain mica (illite), chlorite, tosudite, smectite, and mica–smectite interstratifications. Pottery stones that consist of kaolinite, illite, and pyrophyllite occur as alteration products of acidic volcanic


FIGURE 21.25 Structural sketches of minnesotaite: (a) Perspective view of the idealized structure in which the interlayer tetrahedra share corners to form a chain parallel to Y and (b) in the (001) plane drawing. (From Guggenheim, S., and S.W. Bailey. 1982. The superlattice of minnesotaite. Can. Mineral. 20:579–584.)

rocks, shales, and mudstone, while talc is formed from magnesium silicates, such as olivines, pyroxenes, and amphiboles. Generally speaking, near-neutral hydrothermal solutions generate rock alteration, including the formation of illite, chlorite, and smectite, whereas acid hydrothermal solutions generate the formation of kaolinite.

Most phyllosilicates of hydrothermal origin hold properties defined by the term "clay." The term "clay" is generally applied to the following: (1) a natural material with plastic properties, (2) an essential composition of particles found in a very fine-size fraction, which is customarily defined as particles smaller than 2 μm, and (3) a composition of very fine mineral fragments or particles that are mostly hydrous layer silicates of aluminum or occasionally containing magnesium and iron (Grim and Kodama, 1997). Although, in a broader sense, clay minerals can include virtually any minerals in the clay-size fraction, the definition adopted here is restricted to the hydrous layer silicates, which are conveniently used to distinguish themselves from macroscopic phyllosilicates. In other words, the term "clay minerals" is a synonym of microcrystalline phyllosilicates.

21.3.3 Diagenesis and Low-Grade Metamorphism

Analyses of many ancient sediments in many parts of the world indicate that very old argillaceous (clay-rich) sediments (physilites) are largely composed of illite and chlorite. These clay minerals are also found in carbonate rocks (calcretes). Smectite is a

common component of many shales of Mesozoic and younger ages. As temperature and pressure increase with the progression of diagenesis, clay minerals in sediments under these circumstances change to those stable under given conditions. Therefore, certain sensitive minerals may serve as indicators for various stages of diagenesis. Typical examples are the crystallinity of illite (Kubler, 1966), illite and chlorite polytypes, and the conversion of smectite to illite. The data reported indicate that smectite was transformed into illite through interstratified illite–smectite mineral phases as diagenetic processes advanced. Much detailed work has been devoted to the conversion of smectite to illite in the lower Cenozoic–Mesozoic sediments because such a conversion appears to be closely related to oil-producing processes (Burst, 1969). In the very low-grade metamorphic zone, which is considered to be an intermediate zone between diagenetic and metamorphic zones, the occurrence of rectorite, kulkeite, pyrophyllite, and talc has been reported. Well-crystallized micas and

chlorites are often major components in metamorphic rocks. Smectites are known to occur in sediments of pyroclastic materials as the result of devitrification of volcanic ash in situ. Much discussion appears to favor marine origin for glauconite and nonmarine origin for celadonite (Dunoyer de Sagonzac, 1970; Weaver, 1989; Vielde, 1992).

21.3.4 In Soils, Sediments, and Weathering Products

The formation of the clay minerals by weathering processes is determined by the nature of the parent rock, climate, topography, vegetation, and the time period during which these factors have operated. Climate, topography, and vegetation influence weathering processes by their control of the character and direction of movement of water through the weathering zone. When the dominant movement of water is downward through the alteration zone, any alkaline or alkaline-earth elements tend to be leached and primary minerals containing these components are first degraded and then broken down. If the leaching is intense, then after the removal of the alkalis and alkaline earths, the aluminum or silica may be removed from the alteration zone. This will depend on the pH of the downward-seeping waters. The pH of such water is determined, in turn, by the climate and cover of vegetation. Under warm and humid conditions, with long wet and dry periods, the surface organic material tends to be completely oxidized. The downward-seeping waters, therefore, are neutral or perhaps slightly alkaline and silica will be removed, whereas aluminum and iron will be left behind and concentrated. The result is a lateritic type of soil. Under more temperate conditions, the surface organic material is not completely oxidized and the downward-seeping water contains organic acids. In this case, aluminum and iron oxides are leached and the silicon is left behind; podzolic types of soils will develop. Under these conditions, mica and chlorite tend to be transformed into expandable clay minerals such as vermiculite and smectite or their intergrades as interstratifications. Allophane and imogolite may be present as newly formed clay minerals. In andosols, which are the soils developed on volcanic ash, allophane and imogolite as well as hydrated halloysite and halloysite are dominant components. (Wada and Greenland, 1970) Smectite is usually the sole dominant component in vertisols, which are clayey soils. Smectite and illite, with occasional small amounts of kaolinite, occur in mollisols and prairie chernozemic soils. Illite, vermiculite, smectite, chlorite, and interstratified clay minerals occur in podzolic soils. The alkaline and alkaline-earth elements remain close to the surface and the dry grassland soils (chernozem) containing illite, chlorite, and smectite, will develop. In dry areas, the dominant movement of water is not downward and leaching does not take place. In extreme dry desert areas (desert soils, some aridsols), where the concentration of magnesium is particularly high, the formation of palygorskite–sepiolite minerals has been reported. Kaolinite is the dominant component in laterite soils (oxisols). Clay minerals other than those mentioned above usually occur in various soils as minor components inherited from the parent materials of those soils (cf. Kittrick, 1985).

In general, the process of transportation and sedimentation little affects the weathering products. However, in lagoon–estuary areas, some mineral transformations are possible because environments change from nonmarine to marine and vice versa. As burial sedimentation and compaction continues, temperature and pressure increase. Weathering products in sediments change accordingly. The weathering products are transformed into other clay minerals or decomposed completely to provide constituents required for the neoformation of clay minerals, depending on the chemical environments of the sedimentation and the types of clay minerals present in sediments prior to diagenesis.

In soils, we observe the alteration of phyllosilicates by weathering action, as in a notable case like the transformation of micas into vermiculite, smectite, or randomly interstratified layer silicates (mica–vermiculite, mica–smectite, mica–vermiculite–smectite). On the other hand, we also notice the formation of chloritic minerals from vermiculite or montmorillonite by precipitating hydroxide sheets between the silicate layers, is also noticed as a results of accretion. Other observations have supported some systematic weathering patterns: Kaolinite is formed from aluminum silicates, particularly feldspar. Chlorite is found in igneous rocks as an alteration product from Mg–Fe silicates such as olivines, pyroxenes, amphiboles, and biotite micas, and serpentine is also found in the manner similar to chlorite. In meteorites, the occurrence of iron-rich serpentines in carbonaceous chondrites is reported.

Weathering and subsequent transportation result in the accumulation of sediments at the bottom of lakes, rivers, and oceans. In the Mississippi River system, for example, smectite, illite, and kaolinite are the major components in the upper Mississippi and Arkansas Rivers, whereas chlorite, kaolinite, and illite are the major components in the Ohio and Tennessee Rivers. This is the case for nonmarine conditions. Under marine conditions, at the Gulf of Mexico, for example, smectite, illite, and kaolinite are found to be the major clay mineral composition and their compositions vary from place to place. In some limited regions, it is noteworthy that these compositions are significantly altered by other factors such as airborne effects. The high-kaolinite concentration off the west coast of Africa near the equator reflects this effect.

In a supergene enrichment process, the formation of nickel deposits at New Caledonia is well known, where Ni–serpentine minerals occur in serpentine and peridotite rocks.

21.4 Phyllosilicates in Soil Environments

21.4.1 Introduction

In the foregoing section in which phyllosilicates of hydrothermal origin were discussed, the term "clay minerals" was introduced and the term can be the synonym of phyllosilicates of clay size. The number of phyllosilicate species that occur either in clay size or in a wide range of particle sizes from macroscopic to microscopic is rather limited. Although the numbers of species are small, their quantities are huge. Hence, clay components have great impact on soil environments. The phyllosilicates commonly found in

soils and which belong to the category above include hydrated halloysite, halloysite, kaolinite, micas, chlorites, vermiculites, smectites, and their interstratified minerals. Allophane and imogolite are often associated. The occurrence of clay minerals other than these in soils is either uncommon or rare. Because of fine particles, until relatively recently no appropriate analytical techniques were available by which to determine the precise nature, composition, and structure of clays. Therefore, clays had long been believed to be noncrystalline "colloidal" substances before XRD techniques developed in the 1920s, followed a few years later by improved microscopic and thermal procedures, which established that clays are composed of a few groups of crystalline minerals (Bradley and Grim, 1948). The introduction of electron microscopic methods was very useful to determine characteristic shape and size of clay minerals. Relatively modern analytical techniques such as infrared absorption, neutron diffraction, Mössbauer spectroscopy, and nuclear magnetic resonance have been applied to advance our knowledge of crystal chemistry of clay minerals (Greenland and Hayes, 1978; Wilson, 1992).

21.4.2 Physical Properties

21.4.2.1 Optical Index, Specific Density, and Particle Shape and Size

Clay mineral particles are commonly too small for the measurement of optical properties. Oriented aggregates that are large enough for optical measurements can, however, be prepared by allowing the flake-shaped clay mineral particles to settle from a clay water suspension on a horizontal surface. The particles settle with one flake on top of another so that their basal plane surfaces are essentially parallel. Refractive indices of clay minerals generally fall within a relatively narrow range from 1.47 to 1.68. This range may be subdivided into several groups represented by major mineral species: 1.47–1.52 (allophane, hydrated halloysite); 1.53–1.58 (kaolinite minerals, vermiculite); 1.58–1.65 (nontronite, glauconite, celadonite); and 1.57–1.68 (trioctahedral chlorites). All remaining clay minerals have refractive indices ranging from 1.54 to 1.63, except that smectite minerals have a range from 1.48 to 1.61. In general, iron-rich species show high refractive indices, whereas water-rich porous mineral species have lower refractive indices. Specific densities are as follows: 2.5–2.7 $g \cdot cm^{-3}$ (kaolinite-group minerals); 2.5–2.9 (pyrophyllite, talc, clay micas); 2.6–3.3 (chlorite minerals); 2.6–3.0 (vermiculite); 2.5–2.8 (smectite); ~2 (palygorskite–sepiolite group); 1.7–2.4 (bulk); and 2.6–2.8 (particle) for imogolite and allophane. Table 21.19 lists density, crystallographic units, and optical data of major clay minerals.

The size and shape of clay minerals have been determined by electron micrographs. Well-crystallized kaolinite occurs as well-formed six-sided flakes (Figure 21.26), frequently with a prominent elongation in one direction. Particles with maximum surface dimensions of 0.3 to about 4 μm and thickness of 0.05–2 μm are common. The flakes of disordered kaolinite have poorly developed hexagonal outlines. Halloysite commonly occurs as tubular units with an outside diameter ranging from 0.04 to 0.15 μm (Figure 21.27). Electron micrographs of smectite frequently show

broad undulating mosaic sheets. In some cases, the flake-shaped units are discernible but frequently they are too small or thin to be seen individually without special attention (Oberlin and Méring, 1962). Illite occurs in poorly defined flakes commonly grouped together in irregular aggregates (Figure 21.28). Many of the flakes have a diameter 0.1–0.5 μm and the thinnest flakes are approximately 3 nm thick. Although sizes vary more widely, vermiculite, chlorite, pyrophyllite, talc, and serpentine minerals except for chrysotile are similar in character to the illites. As shown in Figure 21.11, chrysotile occurs in slender tube-shaped fibers with an outer diameter of 10–30 nm. Their lengths commonly reach several microns. Electron micrographs show that palygorskite occurs as elongated laths, singly or in bundles.
FIGURE 21.28 Electron micrograph of illite, from Eldorado, Saskatchewan. Although outline is irregular, it appears as a single crystal (about 1–1.5 μm across). (From Kodama, H., and R.S. Dean. 1980. Illite from Eldorado, Saskatchewan. Can. Mineral. 18:109–118.)

Frequently, the individual laths are many microns in length and 5–10 nm in width. Sepiolite occurs in similar lath-shaped units, but the laths are somewhat thicker and shorter than the palygorskite. As mentioned earlier in the structures, allophane occurs in very small spherical particles (3–5 nm in diameter), individually or in aggregated forms, whereas imogolite occurs in long thread-like tubes of several microns in length. One of the interesting features of layer silicate minerals is their modes of particle association. When a clay suspension of flaky particles flocculates, three different modes of particle association may occur: face-to-face, edge-to-face, and edge-to-edge. These modes are determined by the electrostatical interaction energy between particles, which is influenced by the kind of salt and salt concentration in the medium as well as the surface conditions of the particles.

21.4.2.2 Clay–Water Relations

Clay minerals contain water in several forms. The water may be held in pores and may be removed by drying under ambient conditions. Water also may be adsorbed on the surface of clay mineral structures and in smectites, vermiculites, hydrated halloysite, sepiolite, and palygorskite; this water may occur in interlayer positions or within structural channels. Finally, the clay mineral structures contain hydroxyls that are lost as water at elevated temperatures. The water adsorbed between layers or in structural channels may further be divided into zeolitic (free) and bound waters. The latter is bound to exchangeable cations or directly to the clay mineral surfaces. Zeolitic and bound waters may be removed by heating to temperatures on the order of 100°C–200°C and in most cases, except for hydrated halloysite, is regained readily at ordinary temperatures. Exceptions include those minerals like K-saturated vermiculite in which the interlayer K atoms do not associate with zeolitic water. The bound water is generally agreed to have a structure that is different from bulk water, being more ice-like in its

TABLE 21.20 Cation-Exchange Capacity and Specific Surface Area Data of Representative Clay Minerals, Including Imogolite and Allophane

PI = liquid limit − plastic limit. Numerical figures are expressed in dag kg^{-1}.

structure, even though still liquid. As the thickness of the adsorbed water increases outward from the surface, the nature of the bound liquid water changes abruptly or gradually from ice-like to that of bulk water. Ions and molecules adsorbed on the clay mineral surface exert a major influence on the thickness of the adsorbed water layers and on the nature of this water. The bound liquid water with ice-like characteristics may extend out from the clay mineral surfaces as much as 6–10 nm. Hydroxyl ions are driven off by heating clay minerals to temperatures of 400°C–700°C. The rate of loss of the hydroxyls and the energy required for their removal are specific properties characteristic of the various clay minerals. The reaction for dioctahedral minerals such as kaolinite is abrupt, whereas the loss takes place rather gradually in trioctahedral minerals. This dehydroxylation process results in the oxidation of Fe^{2+} to Fe^{3+} in ferrous-iron-bearing clay minerals. The amount of the adsorbed water is closely related to the surface area of clay minerals that is, of course, determined by their particle size and shape as well as the type of clay minerals. The range of measured surface areas of some clay minerals is given along with that of cation-exchange capacities in Table 21.20. The capacity of water retention of clay minerals is generally proportional to the extent of their surface area (e.g., Ross, 1978). As the water content increases, clays become plastic and then change to a near-liquid state. The amounts of water required for the two states are defined by the plastic and liquid limits. These limits vary with the kind of exchangeable cations and the salt concentration in the adsorbed water. The plastic and liquid limits for different clay minerals are given in Table 21.21. The plasticity index (PI), the difference between the two limits, gives a measure for the rheological (flow) properties of clays. A good example is a comparison of the PI of montmorillonite with that of allophane or palygorskite. The former is considerably greater than the latter, indicating that montmorillonite has a prominent plastic nature. Such rheological properties of clay minerals have great impacts on building foundations, highway construction, chemical engineering, and soil structure in agricultural practice.

21.4.2.3 High-Temperature Reactions

When heated at temperatures beyond dehydroxylation, the clay mineral structure may be destroyed or simply modified, depending on the composition and structure of the clay minerals. In the presence of fluxes, such as iron or potassium, fusion may follow dehydroxylation very quickly. In the absence of such components, particularly for aluminous dioctahedral minerals, a succession of new phases may be formed at increasing temperatures prior to fusion. Thus, in the case of kaolinite, the first high-temperature phase formed is a silica–alumina spinel or γ-alumina plus amorphous silica that is followed at a higher temperature by the development of mullite and cristobalite prior to fusion. In general terms, the first high-temperature phases are a consequence of the original structure of the clay mineral, whereas the later phases are more in accord with the chemical composition. Information on high-temperature-phase change of the clay minerals has been obtained by the use of an x-ray diffractometer to which a small high-temperature furnace is attached. This unit provides x-ray data, while the sample is at an elevated temperature. Information concerning high-temperature reactions is important for ceramic science and industry.

21.4.3 Chemical Properties

21.4.3.1 Layer Charge and Ion Exchange

Depending upon deficiency in the positive or negative charge balance (locally or overall) of mineral structures, clay minerals are able to adsorb certain cations and anions and retain them around the outside of the structural unit in an exchangeable state, generally without affecting its basic silicate structure. These adsorbed ions are easily exchanged by other ions. The exchange reaction differs from simple sorption because it has a quantitative relationship between reacting ions. The range of the cation exchange capacities of the clay minerals is given in Table 21.20 along with specific surface areas. Exchange capacities vary with particle size, perfection of crystallinity, and nature of the adsorbed ion; hence, a range of values exists for a given mineral rather than a single specific capacity. With certain clay minerals—such as imogolite, allophane, and to some extent kaolinite—that have hydroxyls at the surfaces of their structures, exchange capacities also vary

with the pH of the medium, which greatly affects dissociation of the hydroxyls. The ion-exchange charge created as such is called pH-dependent charge or variable charge to distinguish it from the permanent layer charge originating by the ionic substitution in the structure that is independent from pH. The rate of ion exchange varies with clay mineral type and the nature and concentration of the ions. In general, the reaction for kaolinite is most rapid, being almost instantaneous. It is slower for smectites and for sepiolite and palygorskite and requires even long time, perhaps hours or days, to reach completion for illites. Under a given set of conditions, the various cations are not equally replaceable and do not have the same replacing power. Calcium, for example, will replace sodium more easily than sodium will replace calcium. Sizes of potassium and ammonium ions are similar, and the ions are fitted in the hexagonal cavities of the silicate layer. Vermiculite and vermiculitic minerals preferably and irreversibly adsorb these cations and fix them between the layers. Such a preference of one exchangeable cation over another, so-called ion selectivity, may be a tool to exploit layer-charge characteristics of clay minerals in question. Heavy metal ions such as copper, zinc, and lead are strongly attracted to the negatively charged sites on the surfaces of 1:1 layer minerals, allophane and imogolite, which is caused by the dissociation of surface hydroxyls of these minerals.

The ion exchange properties of the clay minerals are extremely important because these properties determine their physical characteristics and economic use. The availability and retention of fertilizer in soils, the adsorption and release of toxic elements in soil and aquatic environments, plasticity, and other clay properties depend to a great extent on ion exchange in general and on the identity of the exchange cation.

21.4.3.2 Solubility

The solubility of the clay minerals in acids varies with the nature of the acid, the acid concentration, the acid to clay ratio, the temperature, the duration of treatment, and the chemical composition of the clay mineral to be attacked. It also varies as a function of heating of the clay minerals and the firing temperatures prior to the acid attack. In general, ferromagnesian clay minerals are more soluble in acids than the aluminum counterparts. Basset (1960) considered that hydroxyl orientation may be an important factor for mica alteration, because in trioctahedral micas hydrogen atoms are oriented directly toward the interlayer K atoms, but in dioctahedral micas, they are tilted away from the interlayer cation. Incongruent dissolutions may result from reactions in a low acid concentration medium where the acid first attacks the adsorbed or interlayer cations and then the components of the octahedral sheet of the clay mineral structure. Frequently with aluminous clay minerals in particular, the tetrahedral silica sheets are not attacked and the morphology of the clay minerals may be retained after solution of all components except silica. In the case of higher acid concentration, such stepwise reactions may not be recognizable and the dissolution appears to be congruent. One of the important factors controlling the rate of dissolution is the concentration in the aquatic medium of the elements extracted from the clay mineral—the greater the concentration of an element in the solution, the more hindered the extraction of the element. In alkaline solutions, a cation exchange reaction first takes place and then the silica part of the structure is attacked. The reaction depends upon the same variables as those stated for acid reactions.

21.4.3.3 Interactions with Inorganic and Organic Compounds

Smectites, vermiculites, and other expansible clay minerals can accommodate relatively large and multivalent inorganic cations between the layers. Because of this multivalency, the interlayer space is only partially occupied by such inorganic cations, which are distributed in the space-like islands. Hydroxy polymers of aluminum, iron, chromium, zinc, and titanium are known examples of such interlayering materials. Most of these are thermally stable and stand as pillars to allow a porous structure in the interlayer space. The resulting complexes, often called pillared clays, exhibit attractive properties as catalysts—namely, large surface area, high porosity, regulated pore size, high solid acidity. Cationic organic molecules, such as certain aliphatic and aromatic amines, pyridines, and methylene blue, may replace inorganic exchangeable cations present in the interlayer of expansible minerals. These organic compounds contain nitrogen atoms, which are able to be positively charged. Polar organic molecules may replace adsorbed water on external surfaces and interlayer positions. Ethylene glycol and glycerol are known to form stable specific complexes with smectites and vermiculites. The formation of such complexes is frequently utilized for the identification of these minerals. On the other hand, potassium acetate can penetrate between kaolin-type silicate layers, which are neutral and held together by hydrogen bonds, and the d_{001} of the mineral expands to 1.42 nm (Wada, 1959, 1961); if dimethyl sulfoxide, DMSO, is used, the expansion is to 1.12 nm (Camazano and Garcia, 1966); if formamide, to 1.0 nm (Weiss et al., 1963). These intercalations with organic compounds are often utilized for the characterization of kaolin minerals. However, experimental results are not always consistent. Caution is required for firm conclusions.

As organic molecules coat the clay mineral surfaces, the nature of clay particle surfaces changes from hydrophilic to hydrophobic, thereby losing its tendency to bind water. Consequently, the affinity of the material for oil increases, so that it can react with additional organic molecules. As a result, the surface of such clay minerals can accumulate organic materials. Some of the clay minerals can serve as catalysts, promoting reactions in which one organic substance is transformed to another on the mineral's surface. Some of these organic reactions develop particular colors, which may be of diagnostic value in identifying specific clay minerals. Organically clad clay minerals are used extensively in paints, inks, and plastics.

21.4.4 Uses of Clays

Clays are perhaps the oldest materials of which man has manufactured various artifacts. The making of fired bricks possibly started some 5000 years ago and was probably the second earliest industry of mankind next to agriculture. The use of clays (probably smectite) as soaps and absorbents was reported in *Natural History* by a Roman author, Pliny the Elder (AD 77). Clays composed of kaolinite are

required for the manufacture of porcelain, whiteware, and refractories. The absence of iron in this clay mineral gives it a white burning color, and the absence of alkalis and alkaline earths gives it a very high fusion temperature that makes it refractory. Whiteware bodies frequently contain talc, pyrophyllite, feldspar, and quartz in addition to the kaolinite clay, in order to develop desirable shrinkage and burning properties. If the kaolinite is poorly crystalline, the clay will have higher plastic and bonding properties.

Clays composed of a mixture of clay minerals, in which illite is most abundant, are used in the manufacture of brick, tile, stoneware, and glazed products. Small proportions of smectite in such clays provide good plastic properties, but in large amounts, smectite is undesirable because it causes too great a degree of shrinkage. Besides the ceramic industry, kaolinite is used as an extender in aqueous-based paints and as filler in natural and synthetic polymers. Smectitic clays (bentonite) are used primarily in the preparation of muds for drilling oil wells. This type of clay, which swells to several times its original volume in water, provides desirable colloidal and wall-building properties. Palygorskite and sepiolite clays also are used because of their resistance to flocculation (grouping or clustering of individual grains or flakes) under high salinity conditions. Certain clay minerals, notably palygorskite, sepiolite, and some smectites, possess substantial ability to remove color bodies from oil. These so-called Fuller's earths are used in processing many mineral and vegetable oils. Because of their large absorbing capacity, Fuller's earths are also commercially used for preparing animal litter trays and oil and grease absorbents. Acid treatment of some smectite clays increases their decolorizing ability. Much gasoline is manufactured by using catalysts prepared from either smectite-type or kaolinite–halloysite-type clay minerals. The preparation may be by acid treatment to modify the structure or by the use of kaolinite and halloysite as a source of alumina and silica for the synthesis of new zeolite-type structures. Large tonnages of kaolinite clays are used as a paper filler and a paper coating to give sheen and carry pigments. The coating clays are washed to free them from grit and then are processed by physical and chemical techniques to improve their whiteness and viscosity. In general, well-crystallized kaolinite that cleaves easily into thin flakes is desired. Palygorskite–sepiolite minerals and acid-treated smectites are used in the preparation of carbonless carbon paper because of the color they develop during reactions with certain colorless organic compounds. Large tonnages of bentonite are used as bonding agents in foundry sands for casting metals. Some poorly crystallized illites and kaolinites are also used for this purpose. Bentonite is combined with lime and coke to pelletize finely ground iron ore, which renders it suitable for use in blast furnaces. Because many clay minerals have aluminum oxide contents on the order of 30%–40%, they are potential ores for aluminum. A variety of processes have been developed to extract this element from clays but clays are not yet competitive with bauxite as a source of aluminum. Extremely large tonnages of reasonably pure clays, preferably of the kaolinite type, would be required for this purpose. Clays have a tremendous number of miscellaneous uses and for each use a particular type of clay with particular properties is important. For example, palygorskite–sepiolite and smectite clays are used as carriers for insecticides and herbicides. Smectite clays are used as plasticizing agents and kaolinite clays are used as extenders and fillers in a large number of organic and inorganic bodies. Kaolinite and smectite clays also are used in a variety of pharmaceutical and medical preparations. For cosmetic products, kaolinite, talc, mica, and smectite clays are used. Smectite and kaolinite clays can be coated with organic molecules for use in many organic systems. Often such organic-clad clays are tailor-made to fit a particular organic system, and thus become an integral part of the system rather than simple diluents. Typical examples are their application to printing inks, oil paints, and lubrication greases. Table 21.22 gives a glimpse of industrial uses of kaolinite, smectite, and palygorskite–sepiolite minerals.

TABLE 21.22 Industrial Uses of Clay Minerals

Kaolinite	Smectite	Palygorskite–Sepiolite
Paper coating	Drilling mud	Drilling fluids
Paper filling	Foundry bond clay	Paint
Extender in paint	Pelletizing iron ores	Paper
Ceramic raw material	Sealants	Ceramics
Filler in rubber	Animal feed bonds	Asphalt emulsions

21.5 Identification of Soil Phyllosilicates

21.5.1 Introduction

Clay mineralogical analysis is a very important first step to elucidate soil behavior, because the clay fraction of soil is most active and influential to the physical, chemical, and biological reactions of soil. X-ray diffraction is a universally accepted method for identifying crystalline mineral components (Brindley, 1951; Brown, 1961; Brindley and Brown, 1980). Unlike the case where only pure crystalline substances are dealt with, soils are complex mixtures of various minerals with a wide range of crystallinity and compositions. Because of these complexities, we often have to compromise with identification and quantification of mineral group rather than mineral species, and the estimation of relative amounts of minerals may often be the best for a given circumstance. Nevertheless, such data provide useful information about mineral translocations and transformations that might have taken place in the soil profiles in question.

21.5.2 X-Ray Diffraction Methods

21.5.2.1 Basics

X-ray diffraction techniques provide a set of reflections from crystalline substances with various diffraction intensities as a function of diffraction angle. The simplest is, therefore, to take standard diffraction diagrams of the principal clay minerals and of the most commonly occurring impurities and to make direct comparison with the diffraction diagrams of unknown clays. For this purpose, *Mineral Powder Diffraction File Data Book* published by JCPDS (Joint Committee on Powder Diffraction Standards) is handy and useful. X-ray reflection takes place from lattice planes with indices, *hkl*, according to the Bragg law,

$$n\lambda = 2d_{hkl} \sin\theta \qquad (21.1)$$

where
  d_{hkl} is lattice spacing for planes *hkl*
  λ is the wavelength
  θ is the glancing angle of reflection
  n is the order of the reflection

The latter two are often called Bragg's angle and the order of Bragg's reflection, respectively. Thus, diffraction experiments measure the quantity from

$$\frac{d_{hkl}}{n} = \frac{\lambda}{2\sin\theta} \qquad (21.2)$$

and this is the lattice spacing for *n*th-order reflection, which is readily understood by introduction of the reciprocal space concept. The Bragg equation gives no intensity information. Diffraction intensities are generally expressed by the relation

$$I = \text{const.(Lp)} \, IFI^2G \qquad (21.3)$$

where
  the constant factor includes all the basic electronic terms, which arises from the fundamental x-ray scattering process
  Lp is the Lorentz-polarization factor
  F is the structure factor that is related to number, kind, and array fashion of the atoms on a lattice plane and the factor can be a positive or negative number
  G is the Laue function that determines diffraction peak profile (Kodama et al., 1971) and, therefore, provides information about the distribution of crystallite sizes and shapes and their crystal imperfections

Figure 21.29 illustrates XRD patterns from oriented samples of muscovite and phlogopite for comparison. They show a series of basal reflections, which can be traced down to at least fifth order. The two minerals have a similar structure except for their octahedral cations, aluminum in muscovite and magnesium in phlogopite. This difference affects the IFI^2 value and reflects on the diffraction pattern. Thus, the ratio $(I_{001}/I_{002})_{\text{phlogopite}}$: $(I_{001}/I_{002})_{\text{muscovite}}$ may be used as one of the criteria for identification. Similarly, this approach is also useful for the determination of chlorite species (Petruk, 1964; Bailey, 1972). If mineralogical data accumulation is the main purpose, more reflections should be observed. Figure 21.30 illustrates differences in diffraction patterns from random and oriented powder specimens of a muscovite. To determine polytypes, not only are the basal reflections required, but the *b* unit cell dimension from the d_{060} reflection and impurities must also be known.

21.5.2.2 Distinguishing among Soil Phyllosilicates

As mentioned earlier, the types of phyllosilicates occurring in soils (and particularly in its clay fraction) are limited to only several layer silicate structures (Figure 21.31), and interstratified layer silicates can also be considered as a combination of two or three basic structures. Obviously from Figure 21.31, the identification of those basic layer structures is due to determination of respective layer thickness (distance normal to the basal plane), which is obtained by XRD as d_{001}-spacing. By choosing effective and critical conditions under which basic layer units are clearly distinguished, criteria for the identification of clay minerals by XRD can be set up (Bradley, 1945). For example, the distinction between smectite and vermiculite is made as follows: Mg-saturation and treated with glycerol expand the d_{001}-spacing of smectite to 1.7–1.8 nm but do not change the d_{001}-spacing at 1.4 nm of vermiculite (Walker, 1949). With the same treatment, chlorite, mica, and kaolinite do not change their d_{001}-spacings at 1.4, 1.0, and 0.72 nm, respectively. On heating at 550°C, however, the structure of kaolinite is destroyed. The d_{001}-spacing at about 1.0 nm of hydrated halloysite contracts to 0.72 nm on heating at 100°C, therefore easily distinguishable from mica. The distinction between vermiculite and chlorite is based on the heat treatment at 550°C or saturation with K$^+$, either of which causes the reduction of the d_{001}-spacing at 1.4–1.0 nm in vermiculite but no change in chlorite. These diagnostic criteria are based on
FIGURE 21.29 XRD patterns of preferred oriented samples: (a) muscovite and (b) phlogopite.
FIGURE 21.30 XRD patterns of muscovite: (a) random sample and (b) oriented sample.
FIGURE 21.31 Diagrammatic representation of principal clay mineral structures, comparing the relative layer thickness of the unit structures. A, Talc–pyrophyllite; B, mica; C, smectite; D, vermiculite; E, chlorite; F, serpentine–kaolinite; and G, hydrated halloysite (halloysite—1.0 nm). In this presentation, tetrahedral and octahedral anions and tetrahedral cations are omitted. (From Sudo, T., S. Shimoda, H. Yotsumoto, and S. Aita. 1981. Electron micrographs of clay minerals. Developments in sedimentology. Vol. 31. Elsevier Scientific Publishing Co., New York.)

generally accepted specific properties of each mineral group for its definition, which may be categorized as follows:

- *Mica.* A 1.0 nm basal spacing and integral series of higher order reflections do not shift upon either hydration or glycerol salvation or heating at 550°C and 700°C.
- *Kaolinite.* Characterized by a series of basal reflections at 0.72, 0.36 nm, and so forth, which do not shift upon either hydration or solvation with glycerol but disappear upon heating at 550°C.
- *Chlorite.* An integral series of basal reflections associated with the largest spacing of 1.4 nm; does not expand by glycerol sorption and does not shift upon heating at 550°C. On heating at 700°C, the intensity of the 1.4 nm peak is enhanced in comparison with those of other peaks. One should bear in mind that the basal intensity ratio varies with chemical composition. The higher order reflections such as third- and fourth-order reflections at 0.473 and 0.355 nm, respectively, may also be used for the distinction of chlorite from kaolinite.
- *Vermiculite.* According to the conventional definition, its Mg form maintains the 1.44 nm basal spacing upon solvation with glycerol and hydration, but the spacing collapses to 1.0 nm upon heating to 550°C, whereas the K form gives the contracted spacing of 1.0 nm without heating. Although its Ca form also shows symptoms similar to those of the Mg form, in some cases, the symptoms become less definite, that is, some of the Ca forms expand beyond 1.44 nm on glycerol solvation depending upon their layer-charge characteristics.
- *Smectite.* Under intermediate humidity (about 50%), the Na form of smectite shows an expansion of its basal spacing to 1.24 nm, and the Ca (also Mg) form to 1.54 nm

(Mooney et al., 1952). These forms expand to 1.8 nm upon solvation with glycerol. Heating to 550°C causes a reduction of the basal spacing to 1.0 nm. It collapses further to 0.96 nm at 700°C, accompanied by its third-order peak at 0.32 nm. This behavior is also a characteristic of vermiculite, but nonexpandable clay minerals like mica retain their third-order peak at 0.333 nm.

After clay mineral components are distinguished at a level of the mineral group category, and if circumstances allow, the procedure of identification continues to determination at the level of mineral subgroup and finally mineral species. To reach the final stage of identification, most likely further tests are needed. For the distinction between montmorillonite and beidellite, for example, the so-called Greene-Kelly test (Greene-Kelly, 1953, 1955) based on the Hofmann–Klemen effect (Hofmann and Klemen, 1950) is often applied. For apparently chloritic minerals derived from vermiculite by acquiring hydroxide sheets between vermiculite silicate sheets, the interlayered vermiculite can be distinguished from chlorite by complexing with sodium citrate to remove the interlayer material. Further information may be obtained from XRD data if complexities due to the combination of clay mineral components themselves and associated impurity are relatively limited.

Ideally, any pretreatment would be avoided to obtain information about mineral components of soil as they are. However, cases are often unavoidable. An extreme example is given in Figure 21.32, where only a pretreatment of the clay fraction by Tiron improves XRD patterns because masking substances are mainly amorphous silica. Many soils cannot disperse without treatment for fractionation. Organic matter, carbonate, and iron oxide removal are often prerequisite. Another example
FIGURE 21.32 XRD patterns (in nm) of a soil clay before and after tiron treatment, exemplifying any suitable chemical pretreatments are often required to obtain decent XRD patterns of soil clays for identification. (From Kodama, H., and G.J. Ross. 1991. Tiron dissolution method to remove and characterize inorganic components in soils. Soil Sci. Soc. Am. J. 55:1180–1187.)

represents effects of various treatments on XRD patterns (Figure 21.33). After fractionation, subsamples (from a clay fraction of podzolic B horizon) were subjected to various treatments. After destruction of organic matter, the <2 mm size fraction was dispersed in water by shaking overnight on an end-over-end shaker, and the clay fraction was collected by sedimentation, saturated with Mg^{2+}, and freeze-dried. This illustrates the necessity of pretreatments for amorphous substances, which mask crystalline components. A quick reference to major chemical dissolution methods is given in Table 21.23. Details of pretreatments may be consulted with appropriate manuals (Bear, 1964; Jackson, 1967; Thorez, 1975; McKeague, 1976; Klute, 1986; Dixon and Weed, 1989; Carter, 1993).

21.5.2.3 Soil Phyllosilicates of Intermediate Nature

In soil environments, especially of the temperate climate region, a majority of the weathering actions on phyllosilicates includes hydration, ion exchange, selective depletion, and partial decomposition of the minerals. As a whole, the actions are considered to be gentle ones. Under these circumstances, micas partially loose their interlayer cations to become hydrated
FIGURE 21.33 XRD patterns of a Mg-saturated and glycerol-solvated clay sample after four separate pretreatments. After organic matter removal, <2 mm fraction was collected from the Whatcom Bf horizon and dispersed by an end-to-end shaker and then the clay fraction was obtained by sedimentation. (From Wang, C., H. Kodama, and N.M. Miles. 1981. Effect of various pretreatments on X-ray diffraction patterns of clay fractions of podzolic B horizons. Can. J. Soil Sci. 61:311–316.)

and expandable. Chlorites gradually experience a mild attack on their hydroxide sheets to alter toward vermiculite-like minerals. Vermiculites may undergo further ion exchange and hydration with their interlayer cations to alter toward smectites. On the contrary, in a lower horizon of the soil profile, an accretion process such as acquiring interlayer substances may take place. By this process, the following transformation routes are also possible: smectites through vermiculites to chlorites, vermiculites to chlorites, micas to chlorites, smectites through vermiculites to micas, vermiculites to micas, and so on. As these actions constantly work on minerals in soil, encountering a phyllosilicate mineral that cannot be correctly identified with a definitive soil phyllosilicate is no surprise. For example, although a soil phyllosilicate indicates a nature similar to vermiculite or smectite, positive identity as either entity may be impossible. This is due to the fact that the soil phyllosilicates possess an intermediate nature. We have observed such cases in the series mica–vermiculite, vermiculite–chlorite, smectite–chlorite, etc. One of the notable accretion processes in soils is the reaction of hydroxyl-Al ions with 2:1 phyllosilicates. Aluminum ions solubilized from minerals hydrolyze readily and are polymerized to form precipitates between expandable silicate layers like vermiculite or smectite to form a chlorite-like mineral. They can be referred to as hydroxyl-Al interlayered vermiculite or hydroxyl-Al interlayered smectite, respectively. These names have been shortened to the acronyms HIV and HIS for which Barnhisel and Bertsch (1989) proposed to standardize the terminology.

21.5.2.4 Interstratified Layer Silicates

As mentioned earlier in the structure of interstratified layer silicates, due to the structural similarities of the clay minerals, interstratified minerals can exist in which individual crystallites are composed of elementary layers of two or more types. Such mixed structures, in some cases, do not show characteristic features of each of the component layers but possess their own identity. They show more or less intermediate nature of the component layers, they are thus called intergrades. Therefore, this intermediate nature may be useful to identify component layers. Table 21.24 gives an example of diagnostic criteria. Interstratified, or mixed layer, clay minerals represent a special case of intergrowths, in relation to a genetic relationship between components. Neglecting all questions regarding interlayer cations, ionic substitution, and layer charge, montmorillonites and vermiculites, for instance, are essentially hydrated varieties of mica having interlamellar water molecules. Instead of water, introduction of hydroxide sheets between silicate layers of these minerals results in chlorite. Therefore, interstratifications among those minerals are expected to be common, as in fact they are. Figure 21.34 gives a graphic presentation for each of the clay minerals as an elementary component, which is known to be composed of an interstratified structure with another elementary component.

The most striking interstratifications occurs when two-component layers A and B alternate regularly to make an interstratified structure, $AB\,AB \ldots$ type, having a long d_{001}-spacing = d_{001}-spacing (layer A) + d_{001}-spacing (layer B). Let P_{AB} be the probability that B succeeds A given that the first layer is A, perfect regularity must satisfy the conditions $P_{AB} = 1$ and $P_{AA} = 0$. As the evaluation of such conditions is not always possible, a practical measure is recommended by the Clay Minerals Society Nomenclature Committee (Bailey et al., 1982). This is based on a statistical test on a well-defined series of at least 10 00-summation spacings ($d_{AB} = d_A + d_B$), for which the suborders are integral. The coefficient of variation

TABLE 21.24 Diagnostic Criteria for Interstratified Minerals in Soils

Type of Interstratification[a]	Glycerol	Humid, >95% RH	Air-Dry, 45% RH	Very Dry, <3% RH	110°C	550°C
Mica–vermiculite	[b]	[b]	1.0–1.4	1.0–1.15	1.0–1.15	1
Mica–chlorite	[b]	[b]	1.0–1.4	[b]	[b]	1.0–1.4
Mica–smectite	0.9–1.0 or ≈1.8	Expansion	1.0–1.55	1.0–1.15	1.0–1.15	1
Vermiculite–chlorite	[b]	[b]	1.4	1.15–1.4	1.15–1.4	1.0–1.4
Vermiculite–smectite	1.4–1.8	Expansion	1.4–1.54	1.15	1.15	1
Chlorite–vermiculite	1.4–1.8	Expansion	1.4–1.54	1.15–1.4	1.15–1.4	1.0–1.4
Mica–vermiculite–chlorite	[b]	[b]	1.0–1.4	Contraction	Contraction	1.0–1.4
Mica–vermiculite–smectite	Expansion	Expansion	1.0–1.54	Contraction	Contraction	1
Vermiculite–chlorite–smectite	Expansion	Expansion	1.4–1.54	Contraction	Contraction	1.0–1.4

(Modified after Sudo, T., S. Shimoda, H. Yotsumoto, and S. Aita. 1981. Electron micrographs of clay minerals. Developments in sedimentology. Vol. 31. Elsevier Scientific Publishing Co., New York.)

(CV) of the d_{00}-values should be less than 0.75 to demonstrate adequate regularity of alternation. The CV is defined as CV = $100s/X$, where the standard deviation for a small sample is $s = [\Sigma(X_i − X)^2/(n − 1)]^{1/2}$, X_i is an individual observed $− x$ d_{00}-value, X is the mean of the X_i values, and n is the number of observed X_i values. In Table 21.25, an example is shown using the case of rectorite–Ca, which is a regularly interstratified mineral, smectite–Ca mica. The observed long d_{001}-spacing is 2.8 nm on glycolation. This agrees with the summation of 1.8 nm for smectite and 1.0 nm for mica when they are glycolated. The XRD data of the rectorite show observable basal reflections up to the 20th in that recording range. The $d \times \ell$ values in the table correspond to observed $− x$ d_{00}-values (X_i). Calculations for this rectorite result in 2.751 nm for the average (X) and 0.463 for the CV value that is much smaller than the recommended value of 0.75. The majority of interstratified layer silicates is not well ordered, so they do not show basal reflection of a long spacing ($d_{AB} = d_A + d_B$) nor a rational integral series of basal reflections.

TABLE 21.25 Example of the CV Test for Evaluating Regularity of Interstratifications

00ℓ	d (Å)	I	d (Å) $\times \ell$

[a] Excluded from CV calculations.

Characterization requires:

1. Determination of component layers A and B (or, and C)
2. Evaluation of the mixing ratio for the component layers A and B, that is, A:B = m:$(1 − m)$, where $0 < m < 1$
3. Probability for layer-stacking sequence as expressed by P_{AA}, P_{AB}, etc

The determination of component layers can be done by choosing appropriate diagnostic tests for them. A relatively simple method is available to evaluate the mixing ratio of two components in an irregularly interstratified structure. The principle of the method is based on the peak migration due to the interference phenomenon of x-rays (Méring, 1949). According to Méring's idea, Figure 21.35 is constructed to explain the principle, using
FIGURE 21.35 Demonstration of Méring's method, in which peak migration is used for evaluating the mixing ratio of two-component layers in an interstratified clay mineral. S_1: Na-saturated rectorite, S_2: Ca-saturated rectorite.

modified rectorite samples. Sodium (Na)-saturated rectorite (S_1) and Ca-saturated rectorite (S_2) were prepared separately. Because the hydration state of Na-saturated smectite differs from that of Ca-saturated smectite under relative humidity at 50%, S_1 gives d_{001} at 2.24 nm and S_2 at 2.54 nm. In this figure, the 00ℓ reciprocal lattice rows of reciprocal spacing $S_1 = 1/d_1$ and $S_2 = 1/d_2$ are given and the heavy lines, such as between S_2 and S_1, indicate the regions in reciprocal space where reflections are predicted to appear as two-component peaks merging together when the two are mixed coherently (in respect with x-rays) without physical segregation and do not constitute a regularly interstratified structure. The assumption is that the peaks move linearly from the position for one pure component toward the nearest position of the other component as the proportions of the components alter. This may not be rigorously correct, but information obtained this way is quite useful. This estimation should be performed by inspecting the peak migrations in as many regions as possible.

As the next step, it is desirable to determine the probability of layer-stacking sequence. A direct Fourier transform method developed by MacEwan and Wilson (1980) and MacEwan et al. (1961) has been applied widely. With mathematical approximation, MacEwan formulates the equation as

$$W_R = \left(\frac{a}{\pi}\right) \Sigma i(s)\cos(\mu_S R) \qquad (21.4)$$

with

$$i(s) = \frac{I_s}{\Theta_s IF_s I^2}$$

where

  W_R is the distribution function defined as the probability of finding another layer at the distance R measured perpendicularly from any layer

  μ_S, I_s, Θ_s, and $IF_s I^2$ are values at the position of the intensity maximum

  $\mu_S = 2\sin\theta/\lambda$

  I_s is the integrated intensity

  Θ_s is the operational function

  $IF_s I^2$ is the layer structure factor

Therefore, a Fourier transform on a series of basal reflections of unknown mixed-layer mineral gives the probability of finding layer B succeeding layer A (P_{AB}) and so on. An application to soil minerals is shown in Figure 21.36. This case happened to be a tertiary system, smectite–vermiculite–mica. The first three peaks (h_A, h_B, h_C) correspond to the probabilities of occurrence of the fundamental component layers, A (smectite), B (vermiculite), and C (mica), respectively. Obviously $P_A + P_B + P_C = 1$, therefore, $P_A = 0.53$, $P_B = 0.27$, and $P_C = 0.20$ were obtained from the observed heights for sample SMJ 1. Knowing the relation between peak heights and occurrence frequencies (for instance, $h_{AA} = P_A P_{AA}$, $h_{AB} = P_A P_{AB} + P_B P_{BA}$, etc.), calculating heights for all possible layer sequences and comparing the calculated with
FIGURE 21.36 Example of direct Fourier transform method by MacEwan on soil clays. (From Kodama, H., and J.E. Brydon. 1968a. A study of clay minerals in podzol soils in New Brunswick, eastern Canada. Clay Miner. 7:295–309.)

the observed allow the probability coefficients to be estimated from the results of the Fourier transform. The direct method is applicable to any interstratifications but caution should be paid to the precision of the results obtained by the Fourier method, which may be affected by premature termination of basal reflection series and assessing the baseline for the obtained occurrence probability curve. Thus, preliminary information concerning the mixing ratio and layer-stacking sequence is acquired and diffraction patterns can be simulated by computer calculations. Several simulation approaches are available (Kakinoki and Komura, 1952, 1954; Sato, 1965, 1973; Reynolds, 1980; Moore and Reynolds, 1989; Yuan and Bish, 2010) for further refinement of the structure of interstratified layer silicates, if cases allow.

21.5.3 Other Instrumental Methods

21.5.3.1 X-Ray Diffraction Photograph Methods

Undoubtedly x-ray diffractometer methods are dominating to collect diffraction data nowadays. However, in the case where only a limited quantity of sample is available, classical photographic methods by the Debye–Scherrer camera is still useful

to obtain maximum information on a mineral in a fraction of milligram. This camera method can avoid preferred orientation to which phyllosilicates have a strong tendency. The determination of polytypes requires details of nonbasal reflections. Therefore, the use of camera techniques is beneficial. Gandolfi camera is one type of a modified Debye–Scherrer x-ray powder diffraction camera. In this camera (Figure 21.37a), the mounted sample rotates around two axes, that is, the sample stage arm rotating around the center of the camera and the sample on a goniometer head itself rotating around an axis tilted 45° to the central rotating axis. With this camera, a single-mineral crystal, or grain, or aggregate, in a fraction of millimeter size, is sufficient to provide adequate powder diffraction patterns without grinding. Examples are presented in Figure 21.38b. Wilson and Clark (1978) developed a method for identifying minerals on thin sections by a combination of optical observations and XRD analysis. This is an interesting area to be explored further for routine application.

21.5.3.2 Methods for Specific Characterization

As discussed in the section on crystal structures, the 1:1 type structures possess hydroxyls in two different octahedral environments, that is, one locates inside at the interface between the octahedral and tetrahedral sheets, and another is exposed to the outside of the octahedral sheet. This is one of the unique characteristics of the 1:1 layer silicates, which may be used for their identification. Infrared absorption spectroscopy can provide details of the OH-stretching bonds in the region of 4000–3000 cm^{-1} in terms of its orientation against the basal plane and its bond distance (O–H$\cdots$O) as affected by octahedral environments, including elemental compositions (Tuddenham and Lyon, 1959; Nakamoto, 1963). The orientation is known to depend on octahedral cation vacancies; therefore, a similar view can be extended to the difference in dioctahedral and trioctahedral 2:1 type structures as well (Serratosa and Bradley, 1958). A number of papers have been published along these lines (only selected ones: Vedder and McDonald, 1963; Vedder, 1964; Farmer, 1974; Robert and Kodama, 1988).

Dealing with iron-bearing phyllosilicates, the actual amount of iron incorporated structurally; the Fe^{2+}:Fe^{3+} ratio as oxidation state; structural configuration, like distribution of these cations between *cis-* and *trans*-octahedral sites; the amount of Fe^{3+} in tetrahedral sites; and occasionally their role in the magnetic nature of the minerals are sought. In the presence of organic matter, the determination of Fe^{2+} is impossible by wet-chemical methods. Application of the Mössbauer effect under these situations is very appropriate. The ^{57}Fe Mössbauer spectroscopy provides parameters such as isomer shift, IS (mm s^{-1}), quadrupole splitting, ΔE_Q (mm s^{-1}), and internal magnetic hyperfine field, H (in *kOe*), if magnetic ordering is present. Most key information is foiled in the quadrupole doublets. Spectra are recorded at temperatures ranging from 4 to 298 K (liquid He to room temperature) to identify the oxidation state, coordination environment, and magnetic exchange interactions occurring in the constituent minerals. The parameters allow the identification of Fe in various (oxy-hydr)oxide and phyllosilicate phases in mixed mineral systems. Analysis of Mössbauer spectra is carried out by computer using a least-squares minimization fitting routine for obtaining the best peak profile. Spectral parameters obtained after refinement may give answers to the questions above (Stucki et al., 1988; Coey, 1988; Murad, 1988; Murad and Cashion, 2004). Among minerals having a chlorite structure, the distinction between iron atoms in the octahedral sheet and iron atoms in the hydroxide sheet has yet to succeed. Murad and Wagner (1991, 1994) succeeded in obtaining detailed characterization of kaolinite minerals and illite by the application of Mössbauer spectroscopy.

The distribution of aluminum atoms that substitute for silicon atoms in the tetrahedral sheet is an interesting subject from a crystallographic point of view (Loewenstein, 1954). Investigations by x-ray methods were performed as done for muscovite by Gatineau (1964). Because the data needed for this purpose require tedious recording and collection of non-Bragg reflections, only specialized laboratories can afford such experiments. Besides the x-ray method, the application of ^{29}Si (and ^{27}Al) magic-angle spinning, solid-state nuclear magnetic resonance spectroscopy was introduced into the research in this line (Herrero et al., 1985). The spectra are obtained as chemical isomer (in this case ^{29}Si) shift (ppm), which is influenced by the chemical environment of the nucleus. The range where resonance spectra appear as a function of polymerization (if true mica, denoted as Q^3 for Si$_3$Al$_1$) and analysis of spectra provides information about Si and Al ordering in the tetrahedral sheet, including the number of next-neighbor Si in layer silicates. Conversely, using the ^{27}Al nucleus, spectra acquired supply information regarding Al and Si ordering and the number of next-neighbor Al in layer silicates (Sans and Serratosa, 1984). Data can be used to compliment each other.

The origin of the total layer charge in phyllosilicates is due to ionic substitutions by atoms of lower valence for those of higher valence like Al^{3+} → Si^{4+}, Fe^{2+} → Fe^{3+}, Mg^{2+} → Al^{3+}. The way in which layer charge is distributed in the structure of a specific phyllosilicate appears to closely relate to the course of weathering or alteration, which the mineral might take in nature. We often believe that phyllosilicates behave erratically, but this is because we normally treat them as if they were totally "structurally homogenous." For instance, when smectite is suspended in water containing Na$^+$ and Ca^{2+}, a demixing phenomenon is observed (Glaeser and Méring, 1954; Glaeser, 1958). Certain phyllosilicates behave as if the distribution of their layer charge is not symmetrical, in other words, the layer charge distribution in the structure has a polarity. In this connection, the *n*-alkylammonium exchange method developed by Lagaly and Wiess (1969) is useful for estimating interlayer charge and characterizing expandable layer silicates by making complexes with the surface of the expandable layer silicates, then the d_{001}-spacings of the complexes are measured. The magnitude of the spacing is related to the size and tilt angle (α) of the *n*-alkylammonium intercalated between the expandable silicate layers. The tilt angle (α), that is, the angle between the alkyl chain and the basal plane of the clay, is related to the layer charge. To evaluate layer charge irregularity, peak positions and profiles of higher order basal reflections may need to be inspected in detail (Lagaly, 1979, 1982; Ghabru et al., 1989) Vali and Koster (1986) developed a method that allows us to make the alkylammonium ion treatment of clay minerals in ultrathin sections for high-resolution transmission electron microscope (HRTEM) observations. The method proved promising and awaits further applications, especially studies on microenvironments.

The task of distinguishing and quantifying the various types of water, that is, physically adsorbed, zeolitic, interlayer, and structural, is not easy. Thermoanalytical methods including thermogravimetric analysis (TGA), differential TGA (DTGA), and differential thermal analysis (DTA) are often applied for this purpose. Although TGA is indispensable for obtaining weight loss, DTGA is helpful to evaluate a critical temperature for distinguishing between water of two different types. The features in a TGA curve are generally too broad to pinpoint precisely the temperatures over which a dehydration reaction occurs (see Figure 21.38).

Water retention is one of the key properties of clay mineral surfaces, as already mentioned. This is due in part to the small particle size and large surface area of the clay minerals, as illustrated by the fact that a handful of clay provides enough surface area to cover an area the size of a football field. Among clay minerals, expandable minerals possess greater surface area than nonexpandable minerals, because in the former surfaces both internal and external to the particles contribute to the total surface area. Surface area measurements by N_2 gas adsorption, notably using the Brunnauer, Emmett, and Teller (BET, method (Brunauer et al., 1938), are often applied for evaluating external surface area.

For total surface area (=external + internal) measurements, glycol retention method (Diamond and Kinter, 1958), ethylene glycol monoethyl ether (EGME) method (Carter et al., 1965), a modified EGME method (Eltantawy and Arnold, 1973), and methylene blue method (Hang and Brindley, 1970) are often applied.

Recent developments in analytical instrumentation enable us to explore objects in much smaller domains as they exist without separation, that is, almost in situ observations (e.g., Tessier, 1990). Perhaps, studies of clay minerals in soil aggregates and in the rhizosphere are certainly interesting. Ideas and concepts regarding mineral alteration mechanisms have long been speculated since Keller and Frederickson (1952) followed by Mortland et al. (1956). This appears recently to revive and improve with modern technologies (Robert and Berthelin, 1984; April and Keller, 1990; Hinsinger et al., 1992; Hinsinger and Jaillard, 1993). Approaches from different perspectives were attempted by Kodama et al. (1994) for the role of clay minerals in the rhizosphere and by Monreal and Kodama (1997) for the role of clay minerals as soil aggregates in microbial activity.

Interactions with microbes have received a great deal of attention. Huang and Schnitzer (1986) summarized an achievement of the workshop organized for interactions of soil minerals with natural organics and microbes. Reviews until 1997 can be seen in *Geomicrobiology* (Banfield and Nealson, 1997). Tazaki and Asada (2007) provided transmission electron micrographs showing intimate association where clay particles attached to a thick wall covering the bacteria. They explained that clay particles and the thick wall, a kind of cellular polymeric substance, are able to protect bacteria from toxic elements such as Hg. The research was performed by an appropriate application of energy-filtering transmission electron microscopy, scanning transmission microscopy equipped with energy dispersive x-ray spectroscopy, optical and fluorescence microscopy, XRD, and atomic absorption spectrometry.

21.5.4 Quantification

21.5.4.1 Basic Theory

Alexander and Klug (1948) showed that the XRD intensity (I_i) from the ith component in a multicomponent mixture can be related to the weight fraction of the component (x_i) by the equation,

$$I_i = \frac{K_i(x_i/\rho_i)}{(\Sigma \mu_i^* x_i)} \tag{21.5}$$

where

ρ_i and μ_i^* are the density and mass absorption coefficient of the component i, respectively

K_i depends upon the nature of component i and the geometry of the apparatus employed

By regarding the mixture of n components as if it consisted of just two components, component 1 to be analyzed and the sum of the other components designated as matrix, Equation 21.5 may be extended to a very useful form:

$$I_1 = \frac{K_1 x_1}{\{\rho_1[x_1(\mu_1^* - \mu_M^*) + \mu_M^*]\}} \tag{21.6}$$

where μ_M^* is the mass absorption coefficient of the matrix. Equation 21.6 is the basic relationship underlying quantitative analysis of multicomponent mixtures with the x-ray diffractometer (Alexander and Klug, 1948; Klug and Alexander, 1954). The diffraction intensity of component 1 is thus related to its concentration in the mixture and to relative mass absorption coefficients of the component and matrix. Because of this relationship, except for the case where $\mu_1^* = \mu_M^*$, that is, the case of a mixture consisting of only polymorphic substances, the intensity–concentration relation is generally not linear. Since mass absorption coefficients are functions of the chemical composition of the absorber and of the wavelength of x-rays irradiated, it is readily understood that the choice of radiation to be employed is important. Practical solutions to Equations 21.5 and 21.6 are discussed in the following section.

21.5.4.2 Intensity–Concentration Calibration Curve

For general analytical purposes, one possible solution of Equation 21.6 is to establish intensity–concentration working curves from multicomponent standard synthetic mixtures that simulate a natural system in question. This approach has been attempted for the quantitative estimation of clay minerals by Talvenheimo and White (1952) among others. However, numerous combinations of mineral associations occur in nature, so to cover all possible cases by preparing synthetic standard mixtures is not practical. Thus, this approach is necessarily restricted to simple systems. One of the more practical solutions to the analysis of complicated multicomponent systems may be to compare intensities of two components in a multicomponent mixture and to relate them to their weight proportions. By introducing the average mass absorption coefficient, μ^*, for the mixture, we can simplify Equation 21.5 to

$$I_i = K_i' \left[\frac{x_i}{(\rho_i \mu^*)} \right] \tag{21.7}$$

Then a comparison between intensities of the ith and jth components produces the relation independent of μ^* (Brindley, 1961) as follows:

$$\frac{I_i}{I_j} = \frac{K_i' x_i \rho_j}{(K_j' x_j \rho_i)} = K'' \left(\frac{x_i}{x_j} \right) \tag{21.8}$$

where K'' includes all constants, K_i', K_j', ρ_i, and ρ_j, for two mineral components i and j. Equation 21.8 suggests a linear relationship between the intensity ratio ($I_i{:}I_j$) and the ratio of weight fractions ($x_i{:}x_j$) for the two mineral components. Therefore, if the K'' is evaluated experimentally by synthetic mixtures, the relative weight fractions in unknowns can be determined from measurements of intensity ratios. In a multicomponent system, the weight fraction of each mineral component can be estimated by integration of the results on mineral pairs, which cover all mineral species in the sample. This method was applied to clay minerals by Theisen and Bellis (1964).

21.5.4.3 Internal Standard Method

The use of an internal standard also permits quantitative analysis without any direct knowledge of the mass absorption coefficients of components (μ_i^*), since the method is based on a relation similar to Equation 21.8. Suppose that a known and constant amount of an internal standard, which will be designated by the subscript "s" is added to an unknown mixture. Then the weight fraction of component 1 (x_1) in the original mixture is changed to x_1', which is expressed by the relation, $x_1 = x_1'/(1 - x_S)$. This relation can be derived as follows: since $w_S/x_S = (w + w_S)$, where w and w_S are the total sample weight before the addition of the standard and the weight of the standard added, respectively; thus, $1 - x_S = w/(w + w_S)$. On the other hand, $x_1' = w_1/(w + w_S)$ and $x_1 = w_1/w$, therefore $x_1 = x_1'/(1 - x_S)$. Taking the intensity ratio of I_1 to I_S in a manner similar to Equation 21.8, we obtain the relation

$$\frac{I_1}{I_S} = \frac{K_1 x_1' \rho_S}{K_S x_S \rho_1} = \frac{[K_1' x_1(1 - x_S)\rho_S]}{K_S x_S \rho_1} \qquad (21.9)$$

All components but x_1 in the right-hand term of Equation 21.9 are regarded as constant; Equation 21.9 can, therefore, be arranged to

$$x_1 = k\left(\frac{I_1}{I_S}\right) \qquad (21.10)$$

Thus, the concentration of component 1 is proportional to the intensity ratio $I_1{:}I_S$ alone and independent of mass absorption coefficients of a specific mineral and matrix. This method has been applied to clays and related minerals using internal standards such as fluorite (CaF_2) (Alexander and Klug, 1948), boehmite ($AlOOH$) (Brindley and Kurtossy, 1961), $Zn(OH)_2$ (Mossman et al., 1967), and pyrophyllite (Mossman et al., 1967).

21.5.4.4 Standard Additional Method (Spike Method)

As described by Brindley and Udagawa (1960), this method involves an addition of a known amount of a pure mineral component to a sample in which the mineral component is to be analyzed. The method is useful if the characteristics of the mineral component in the sample closely resemble those of the pure mineral component to be added. If the change in the average

μ^* of Equation 21.7 by this addition can be neglected, then the ratio ($I_1'{:}I_1$) of intensities of component 1 being analyzed before (I_1) and after (I_1') should be directly proportional to the ratio of weight fractions as follows (Brindley and Udagawa, 1960):

$$\frac{I_1'}{I_1} = \frac{(x_1 + x_1')}{[x_1(1 + x_1')]} \qquad (21.11)$$

where the right-hand term is the weight fraction of the component after the addition of the component to the sample. It should be borne in mind that the optimum amount of the pure mineral added depends upon the initial amount of the mineral component in the sample. As a general guide, 25%–100% of the initial amount may be recommended.

21.5.4.5 External Standard Method (Direct Method)

This method requires mass absorption coefficient measurements and has been applied by Williams (1959), Norrish and Taylor (1962), and others. Such measurements are, however, rather time-consuming and the method has only limited application to complicated mineral mixtures in soils.

21.5.4.6 Estimation Based on Intensity Factor Ratios

The diffraction intensity, I_{hkl}, of the hkl reflection is proportional to the square of the structure factor, F_{hkl}, thus, $I_{hkl} \sim KIF_{hkl}I^2$, where K depends upon experimental conditions and the value of F is related to the numbers and kinds of atoms involved in the reflection plane hkl of a mineral structure. Consider a mixture consisting of two minerals A and B with equal amounts and let I_A and I_B be the diffraction intensities from any reflection planes of minerals A and B, respectively. The ratio $I_B{:}I_A$ should be constant regardless of the absolute amounts of both minerals, and this constant factor, k, may be expressed by IF_BI^2/IF_AI^2, where F_A and F_B are the structure factors for the corresponding reflections of minerals A and B, respectively. The I_A is, therefore, equal to I_B/k. If the amounts of minerals A and B are not the same, they would be proportional to $I_A/1$ and I_B/k, respectively. This is the basic concept for the quantification method based on the intensity factor ratios. The concept can be extended easily to multi-component systems.

The preferred orientation method is widely applied to identify clay minerals. It is, therefore, very convenient and practical that the basal reflections are used for quantification. The basal intensity factor ratios may be obtained (a) directly from structure factor calculations or (b) by graphical approximation from squared moduli of layer structure factors prepared by Bradley (1953), MacEwan et al. (1961), and Cole and Lancucki (1966) for various types. By these approaches, Johns et al. (1954) first attempted the quantification of clay minerals and many investigators followed (e.g., Weaver, 1958; Schultz, 1960, 1964; Dell, 1973). Another way to evaluate the factors is by an experimental determination based upon synthetic standard mixtures. The advantage of the latter is that the factors evaluated can include all necessary correction factors due to experimental conditions

as well as the intensity factor. Therefore, the factors can be applied immediately to estimate quantities of clay minerals, as long as the experimental conditions are the same as those for the synthetic standard mixtures from which the factors were evaluated. In general practice for the quantification of clay minerals, intensity factors are determined using a series of binary mineral systems, like minerals *A* and *B,* with equal amounts at several different levels. Similar experiments should be extended to other binary systems like minerals *A* and *C*, or *A* and *D*, and so on. Obviously, the intensity factors of mineral *A* are expected for normalization for the whole. The mineral illite is often chosen for this purpose due to various merits. This approach was chosen by Oinuma et al. (1961). Most clay minerals vary in crystallinity and composition, which greatly affect their basal reflection intensities. Because of this, quantitative estimations made from these intensity factor methods are crude in comparison with those done by methods described in previous sections. In view of difficulties due to variations in clay minerals, however, such an approach is believed to be the best compromise.

21.5.4.7 General Outline for Soil Mineral Quantification

Since soils are complex mixtures of substances of varying degrees of crystallinity ranging from amorphous to strongly crystalline, achieving quantitative analysis with a comparable precision for all mineral components at the same time is almost impossible. Although a major emphasis should be put on clay minerals that usually constitute a large portion of crystalline substances in the clay-size fraction of soils, depending upon the type of minerals involved, a more precise estimation may be made by choosing a suitable method for a specific case. Thus, the general outline adapted in our laboratory for the soil mineral quantification is a combination of methods as follows (Kodama et al., 1977):

1. The method using intensity factor ratios for clay minerals (phyllosilicates) in general
2. The intensity–concentration calibration method for quartz
3. The internal standard method for hematite and goethite
4. A combination of the intensity–concentration and internal standard methods for feldspars and amphiboles
5. The standard addition method for minerals such as calcite, dolomite, gypsum, serpentine minerals, talc, pyrophyllite, and jarosite, which occur less frequently in soils and whose crystallinities do not vary much so that a standard representing the mineral to be analyzed in a sample is easily available

Addendum

After the preparation of this chapter, the author received a copy of the following manuscript: The Mica Group, *In Kluwer Encyclopaedia of Mineralogy* by A.E. Lalonde, 90 pp with nine figures. This appears to be available online.

Appendix

Glossary of Phyllosilicates

Notes:

1. Every valid mineral species names are listed in bold face.
2. Mineral group names are in italic.
3. Majority of interstratified minerals listed here are given in a form of binary system expressed by mineral group names (mica–smectite, vermiculite–smectite, etc.).

A

Aliettite 1:1 regular interlayering of talc–trioctahedral smectite-group mineral, *Interstratified Layer Silicate Group*

Allevardite = **Rectorite**

Alurgite = magnesian manganiferous **Muscovite**

Amesite $Mg_2Al(Si,Al)O_5(OH)_4$, *Serpentine–Kaolin Group*
> Amesite-2*H*
> Amesite-6*R*

Anandite $Ba,K(Fe^{2+},Mg)_3(Si,Al,Fe^{3+})_4O_{10}(O,OH)_2$, *Brittle Mica Group*
> Anandite-2*M*₁
> Anandite-2*Or*

Anauxite = mixture of kaolinite and amorphous silica

Annite $K(Fe^{2+})_3(AlSi_3)O_{10}(OH,F)_2$, *True Mica Group*

Antigorite $(Mg,Fe)_3Si_2O_5(OH)_4$, *Serpentine–Kaolin Group*

Aphrosiderite = ferroan **Clinochlore**

Aspidolite = sodium **Phlogopite**

Attapulgite = **Palygorskite**

B

Baileychlore $(Zn,Fe^{2+},Al,Mg)_6(Si,Al)_4O_{10}(OH)_8$, *Chlorite Group*

Bannisterite $KCa(Fe,Mn,Zn,Mg)_{20}(Si,Al)_{32}O_{76}(OH)_{16} \cdot 4–12H_2O$, *Modulated Layer Silicate Group*

Baumite = zirconian Caryopilite, zirconian **Greenalite**

Bementite $Mn_7Si_6O_{15}(OH)_8$, *Modulated Layer Silicate Group*

Beidellite $(Na,Ca)_{0.3}(Al)_2(Si,Al)O_{10}(OH)_2 \cdot nH_2O$, *Smectite Group*

Bentonite = (a) impure **Montmorillonite**, (b) **Beidellite**

Berthierine $(Fe^{2+},Fe^{3+},Mg)_{2–3}(Si,Al)_2O_5(OH)_4$, *Serpentine–Kaolin Group*
> Berthierine-1*M*

Biotite $K(Mg,Fe^{2+})_3(Al,Fe^{3+})Si_3O_{10}(OH,F)_2$, *True Mica Group*

Bityite $CaLiAl_2(AlBeSi_2)O_{10}(OH)_2$, *Brittle Mica Group*

Bowingite = **Saponite**

Bramallite = sodian **Muscovite (Illite)**

Brandisite = **Clintonite**

Brindleyite $(Ni,Mg,Fe^{2+})_2Al(Si,Al)O_5(OH)_4$, *Serpentine–Kaolin Group*

Brunsvigite = **Chamosite**

C

Cardenite = ferrian **Saponite**

Carlosturanite $(Mg,Fe^{2+},Ti)_{21}(Si,Al)_{12}O_{28}(OH)_{34}$, *Modulated Layer Silicate Group*

Caryopilite $(Mn^{2+},Mg)_3Si_2O_5(OH)_4$, *Modulated Layer Silicate Group*

Celadonite $K(Mg,Fe^{2+})_3(Fe^{3+},Al)Si_4O_{10}(OH)_2$, *True Mica Group*

Cerolite = (a) talc; (b) mixture of *serpentine* and **Stevensite**

Chamosite $(Fe^{2+},Mg,Fe^{3+},Al)_5Al(Si_3Al)O_{10}(OH,O)_8$, *Chlorite Group*
 Chamosite-7Å

Chernykhite $(Ba,Na)(V^{3+},Al)_2(Si,Al)_4O_{10}(OH)_2$, *True Mica Group*

Chlorite   A mineral group, with general structural formula, $(Mg,Fe^{2+},Fe^{3+},Li,Al,Mn,Ni,Zn)_{4-6}(Si,Al,B,Fe^{3+})_4O_{10}(OH,O)_8$

Chlorite–mica   See Mica–chlorite

Chlorite–smectite   Interlayering of chlorite and smectite minerals with various mixing ratio and layer-stacking sequence of the two components, *Interstratified Layer Silicate Group*

Chlorite–talc   See Talc–chlorite

Chlorite–vermiculite   Interlayering of chlorite and vermiculite minerals with various mixing ratio and layer-stacking sequence of the two components, *Interstratified Layer Silicate Group*

Chloropal = **Nontronite**

Chrysocolla $(Cu^{2+},Al)_2H_2Si_2O_5(OH)_4 \cdot nH_2O$, *Serpentine–Kaolin Group*

Chrysolite $Mg_3Si_2O_5(OH)_4$, *Serpentine–Kaolin Group*
 Chrysolite-1M_{cl}
 Chrysolite-2M_{cl}
 Chrysolite-2Or_{cl}

Clinochlore $(Mg,Fe^{2+})_5Al(Si_3Al)O_{10}(OH,O)_8$, forms a series with Chamosite, *Chlorite Group*

Clinochrysotile = **Chrysolite**-1M_{cl}

Clintonite $Ca(Mg,Al)_3(Al_3Si)O_{10}(OH)_2$, *Brittle Mica Group*
 Clintonite-1M
 Clintonite-2M

Cookeite $Li,Al_4(Si_3Al)O_{10}(OH)_8$, *Chlorite Group*

Corrensite   1:1 Regular interlayering of trioctahedral chlorite–smectite or vermiculite-group mineral, with approximate structural formula $(Mg,Fe,Al)_9(Si,Al)_8O_{20}(OH,O)_{10} \cdot nH_2O$, *Interstratified Layer Silicate Group*

Corundphilite = ferroan **Clinochlore**

Cronstedtite $Fe_3^{2+}Fe^{3+}(Si,Fe^{3+})_2O_5(OH)_4$, *Serpentine–Kaolin Group*
 Cronstedtite-1H

D

Daphnite = manganoan **Chamosite**

Delessite = magnesian **Chamosite** or ferrous **Clinochlore**

Deweylite = mixture of **Chrysotile** or **Lizardite** and **Stevensite**

Diabantite = ferroan **Clinochlore**, **Chamosite**

Dickite $Al_2Si_2O_5(OH)_4$, polymorphic relationship with kaolinite and nacrite,

Donbassite $Al_{4-5}(Si_3Al)O_{10}(OH)_8$, *Chlorite Group*

E

Eastonite = (a) **Biotite**, (b) **Vermiculite**, (c) **Phlogopite**

Endellite = (a) Hydrated halloysite, (b) **Halloysite**

Ephesite $NaLiAl_2(Al_2Si_2)O_{10}(OH)_2$, *Brittle Mica Group*

F

Falcondoite $(Ni,Mg)_4Si_6O_{15}(OH)_2 \cdot 6H_2O$, a nickeloan variety of **Sepiolite**, *Sepiolite–Palygorskite Group*

Ferriannite (Ferri-annite) $K(Fe^{2+},Mg)_3(Fe^{3+},Al)Si_3O_{10}(OH,F)_2$, *True Mica Group*

Ferriphlogopite = ferrian **Phlogopite**

Ferripyrophyllite $Fe_2^{3+}Si_4O_{10}(OH)_2$, compare **Pyrophyllite**

Fraipontite $(Zn,Al)_3(Si,Al)_2O_5(OH)_4$, *Serpentine–Kaolin Group*

G

Ganophyllite $(K,Na)_2(Mn,Al,Mg)_8(Si,Al)_{12}O_{29}(OH)_7 \cdot 8-9H_2O$, *Modulated Layer Silicate Group*

Garnierites = general term for hydrous nickel silicates, mainly **Népouite**, **Falcondoite**

Ghassoulite = **Hectorite**

Glauconite $(K,Na)(Fe^{3+},Al,Mg)_2(Si,Al)_4O_{10}(OH)_2$, *True Mica Group*

Gonyerite $(Mn^{2+},Mg)_5Fe^{3+}(Si_3Fe^{3+})O_{10}(OH)_8$, *Modulated Layer Silicate Group*

Greenalite $(Fe^{2+},Fe^{3+})_{2-3}Si_2O_5(OH)_4$, *Modulated Layer Silicate Group*

Griffithite = ferroan **Saponite**

Grovesite = **Pennantite**

H

Halloysite $Al_2Si_2O_5(OH)_4$, *Serpentine–Kaolin Group*
 Halloysite-7 Å $Al_2Si_2O_5(OH)_4$
 Halloysite-10 Å $Al_2Si_2O_5(OH)_4 \cdot 2H_2O$

Halloysite—hydrated halloysite   Interlayering of halloysite-7 Å and halloysite-10 Å, with various mixing ratio and stacking sequence of the two components, *Interstratified Layer Silicate Group*

Hectorite $Na_{0.3}(Mg,Li)_3Si_4O_{10}(F,OH)_2$, *Smectite Group*

Hendricksite $K(Zn,Mg,Mn^{2+})_3(Si_3Al)O_{10}(OH)_2$, *True Mica Group*

Hydrated halloysite = Halloysite-10 Å

Hydrobiotite   1:1 Regular interlayering of biotite and vermiculite, *Interstratified Layer Silicate Group*

Hydromicas   K-poor and H_2O-rich **Muscovite** (illite); altered **Muscovite**

Hydromuscovite = Hydromicas

I

Illite $(K,H_3O)(Al,Mg,Fe)_2(Si,Al)_4O_{10}[(OH)_2,H_2O]$, *True Mica Group*

Illite–chlorite   Compare Mica–chlorite, *Interstratified Layer Silicate Group*

Illite–smectite   Compare Mica–smectite, *Interstratified Layer Silicate Group*

Illite–vermiculite   Compare Mica–vermiculite, *Interstratified Layer Silicate Group*

K

Kämmererite = chromian **Clinochlore**

Kaolin A general term for kaolin minerals, with Serpentine forms *Serpentine–Kaolin Group*

Kaolin–smectite Interlayering of kaolin and smectite minerals with various mixing ratio and various stacking sequence of the two components, *Interstratified Layer Silicate Group*

Kaolinite $Al_2Si_2O_5(OH)_4$, *Serpentine–Kaolin Group*

Kellyite $(Mn^{2+},Mg,Al)_3(Si,Al)_2O_5(OH)_4$, *Serpentine–Kaolin Group*

Kerolite (a) Mixture of serpentine and stevensite; (b) talc

Kinoshitalite $(Ba,K)(Mg,Mn,Al)_3(Si,Al)_4O_{10}(OH,F)_2$, *Brittle Mica Group*

Kotschubeite = ferran **Clinochlore**

Kulkeite $(Na_{0.4}Mg_8Al(Al,Si_7)O_{20}(OH)_{10}$, a 1:1 interlayering of talc and trioctahedral chlorite, *Interstratified Layer Silicate Group*

L

Lepidolite $K(Li,Al)_3(Si,Al)_4O_{10}(F,OH)_2$, *True Mica Group*

Lepidolite-1*M*

Lepidolite-2*M*₁

Lepidolite-2*M*₂

Lepidolite-3*T*

Leptochlorite = iron-rich *Chlorite*, mainly **Chamosite**

Leuchtenbergite = iron-deficient **Clinochlore**

Lizardite $Mg_3Si_2O_5(OH)_4$, *Serpentine–Kaolin Group*

Lizardite-1*T*

Lizardite-2*H*

Lizardite-6*T*

M

Manganopyrosmalite *Modulated Layer Silicate Group*

Margarite $CaAl_2(Al_2Si_2)_4O_{10}(OH)_2$, *Brittle Mica Group*

Margarite-2*M*

Masutomilite $K(Li,Al,Mn^{2+})_3(Si,Al)_4O_{10}(F,OH)_2$, *True Mica Group*

Medomontite = mixture of **Chrysocolla** and mica or hydromica

Metahalloysite = Halloysite-7 Å, dehydrated halloysite

Mica A mineral group, with general structural formula, $(Ba,Ca,Cs,H_3O^+,K,Na,NH_4)(Al,Cr,Fe^{2+},Fe^{3+},Li,Mg,Mn^{2+},Mn^{3+},V,Zn)_{2-3}(Al,Be,Fe^{3+},Si)_4O_{10}(OH,F)_2$

Mica–chlorite Interlayering mica and chlorite minerals with various mixing ratio and layer-stacking sequence of the two components, *Interstratified Layer Silicate Group*

Mica–smectite Interlayering of mica and smectite minerals with various mixing ratio and layer-stacking sequence of the two components, *Interstratified Layer Silicate Group*

Mica–vermiculite Interlayering of mica and vermiculite minerals with various mixing ratio and layer-stacking sequence of the two components, *Interstratified Layer Silicate Group*

Minnesotaite $(Fe^{2+},Mg)_3Si_4O_{10}(OH)_2$, *Modulated Layer Silicate Group*

Montdorite = aluminum-deficient **Biotite**

Montmorillonite $(Na,Ca)_{0.3}(Al,Mg)_2Si_4O_{10}(OH)_2 \cdot nH_2O$, *Smectite Group*

Muscovite $KAl_2(Si_3Al)O_{10}(OH,F)_2$, *True Mica Group*

Muscovite-1*M*

Muscovite-2*M*₁

Muscovite-2*M*₂

Muscovite-3*T*

N

Nacrite $Al_2Si_2O_5(OH)_4$ polymorphic relationship with **Dickite**, **Halloysite**, and **Kaolinite**, *Serpentine–Kaolin Group*

Nanpiningite $Cs(Al,Mg,Fe^{2+},Li)_2(Si_3Al)O_{10}(OH,F)_2$, *True Mica Group*

Népouite $Ni_3Si_2O_5(OH)_4$, *Serpentine–Kaolin Group*

Nimite $(Ni,Mg,Fe^{2+})_5Al(Si_3Al)O_{10}(OH)_8$, *Chlorite Group*

Nontronite $Na_{0.3}Fe_2^{3+}(Si,Al)_4O_{10}(OH)_2 \cdot nH_2O$, *Smectite Group*

Norrishite $KLiMn_2^{3+}Si_4O_{12}$, *True Mica Group*

O

Odinite $(Fe^{3+},Mg,Al,Fe^{2+})_{2.5}(Si,Al)_2O_5(OH)_4$, *Serpentine–Kaolin Group*

Odinite-1*M*

P

Palygorskite $(Mg,Al)_2Si_4O_{10}(OH)$ $4H_2O$, *Sepiolite–Palygorskite Group*

Paragonite $NaAl_2(Si_3Al)O_{10}(OH)_2$, *True Mica Group*

Parsettensite $(K,Na,Ca)(Mn,Al)_7Si_8O_{20}(OH)_8 \cdot 2H_2O$, *Modulated Layer Silicate Group*

Pecoraite $Ni_3Si_2O_5(OH)_4$, dimorphic relationship with népouite, *Serpentine–Kaolin Group*

Pennantite $Mn_5^{2+}Al(Si_3Al)O_{10}(OH)_8$, *Chlorite Group*

Penninite = **Clinochlore**

Phengite $KAl_{1.5}(Mg,Fe^{2+})_{0.5}(Si_{3.5}Al_{0.5})O_{10}(OH,F)_2$, *True Mica Group*

Phlogopite $K(Mg,Fe^{2+})_3Si_3AlO_{10}(F,OH)_2$, *True Mica Group*

Polylithionite $KLi_2AlSi_4AlO_{10}(F,OH)_2$, *True Mica Group*

Preiswerkite $Na(Mg_2Al)(Si_2Al_2)O_{10}(OH)_2$, *True Mica Group*

Prochlorite = ferran Clinochlore

Pseudophite = **Clinochlore**

Pyrophyllite $Al_2Si_4O_{10}(OH)_2$, *Talc–Pyrophyllite Group*

Pyrophyllite-2*M*

Pyrophyllite–smectite Interlayering of pyrophyllite and smectite minerals with various mixing ratio and layer-stacking sequence of the two components, *Interstratified Layer Silicate Group*

R

Rectorite $(Na,Ca)Al_4(Si,Al)_8O_{20}(OH)_4 \cdot 2H_2O$, a 1:1 interlayering of dioctahedral mica and dioctahedral smectite and rectorite may further be distinguished into the following:

Ca–Rectorite = the mica-like layer whose composition is similar to that of margarite

Na–Rectorite = rectorite in which its nonexpandable layer is similar to paragonite

K–Rectorite = the mica-like layer whose composition is similar to that of muscovite

Ripidolite = ferran **Clinochlore**, magnesian **Chamosite**

Roscoelite $K(V^{3+},Al,Mg)_2(Si,Al)_4O_{10}(OH)_2$, *True Mica Group*

S

Saponite $(Ca,Na)_{0.3}(Mg,Fe^{2+})_3(Si,Al)_4O_{10}(OH)_2 \cdot 4H_2O$, _Smectite Group_

Iron saponite = saponite with Fe > Mg in its octahedral sheet

Sauconite $Na_{0.3}Zn_3(Si,Al)_4O_{10}(OH)_2 \cdot 4H_2O$, _Smectite Group_

Sepiolite $Mg_4Si_6O_{15}(OH)_2 \cdot 6H_2O$, _Sepiolite–Palygorskite Group_

Septechlorite = amesite, antigorite, berthierine, chrysotile, cronstedtite, lizardite, etc., trioctahedral kaolinite–serpentine minerals

Sericite = (a) **Muscovite (illite)**; (b) fine-grained mica-like minerals

Serpentine = a group name for minerals with the general formula, $(Mg,Fe,Ni)_3Si_2O_5(OH)_4$

Seybertite = **Clintonite**

Sheridanite = aluminum **Clinochlore**, ferroan **Clinochlore**

Shirozulite $KMn_3^{2+}(Si,Al)_4O_{10}(OH)_2$, _True Mica Group_

Siderophyllite $KFe_2^{2+}Al(Al_2Si_2)_4O_{10}(F,OH)_2$, _True Mica Group_

Smectite represent the smectite-group minerals, with general formula $X_{0.3}Y_{2-3}Z_4O_{10}(OH)_2 \cdot nH_2O$ where X = Ca, Li, Na; Y = Al, Cr, Cu, Fe^{2+}, Fe^{3+}, Li, Mg, Ni, Zn; Z = Al, Si, _Smectite Group_

Smectite–chlorite See Chlorite–smectite

Smectite–illite Compare Mica–smectite

Smectite–kaolin See Kaolin–smectite

Smectite–mica See Mica–smectite

Smectite–pyrophyllite See Pyrophyllite–smectite

Smectite–talc See Talc–smectite

Smectite–vermiculite See Vermiculite–smectite

Stevensite $Ca_{0.15}Mg_3Si_4O_{10}(OH)_2$, _Smectite Group_

Stilpnomelane $K(Fe^{2+},Mg,Fe^{3+})_8(Si,Al)_{12}O_{10}(O,OH)_{27}$, _Modulated Layer Silicate Group_

Sudoite $Mg_2(Al,Fe^{3+})_3Si_3AlO_{10}(OH)_8$, _Chlorite Group_

Swinefordite $(Ca,Na)_{0.3}(Li,Mg)_2(Si,Al)_4O_{10}(OH,F)_2 \cdot 2H_2O$, _Smectite Group_

T

Taeniolite $K(LiMg_2)Si_4O_{10}(F,OH)_2$

Talc $Mg_3Si_4O_{10}(OH)_2$, _Talc–Pyrophyllite Group_

Talc–chlorite Interlayering of talc and chlorite minerals with various mixing ratio and layer-stacking sequence of the two components, _Interstratified Layer Silicate Group_

Talc–saponite Compare Talc–smectite

Talc–smectite Interlayering of talc and smectite minerals with various mixing ratio and layer-stacking sequence of the two components, _Interstratified Layer Silicate Group_

Tarasovite A regular interstratified mineral of illite (I) and smectite (S) with nearly _IIIS_ sequence. The ratio = 0.75:0.25, _Interstratified Layer Silicate Group_

Thuringite = ferrian **Chamosite**

Tobelite $(NH_4,K)Al_2(Si_3Al)O_{10}(OH)_2$, _True Mica Group_

Tosudite A 1:1 interlayering of chlorite and a smectite-group phase, with composition, $Na_{0.5}(Al,Mg)_6(Si,Al)_8O_{18}(OH,F)_{12} \cdot 5H_2O$, _Interstratified Layer Silicate Group_

Trilithionite $K(Li_{1.5}Al_{1.5})(Si_3Al)_4O_{10}(F,OH)_2$, _True Mica Group_

V

Vermiculite A majority of this mineral are trioctahedral and with a sample composition, $(Mg,Ca)_{0.3}(Mg_{2.5}Fe_{0.5})(Al_{1.2}Si_{2.8})O_{10}(OH)_2 \cdot 4H_2O$, _Vermiculite Group_

Vermiculite A group name for minerals with the general formula, $(Mg,Ca)_{0.35}(Mg,Fe,Al)_3(Al,Si)_4O_{10}(OH)_2 \cdot 4H_2O$

Vermiculite–mica See Mica–vermiculite

Vermiculite–chlorite See Chlorite–vermiculite

Vermiculite–smectite Interlayering of vermiculite and smectite minerals with various mixing ratio and layer-stacking sequence of the two components, _Interstratified Layer Silicate Group_

Volkonskoite $Ca_{0.3}(Cr^{3+},Mg)_2(Si,Al)_4O_{10}(OH)_2 \cdot 4H_2O$, _Smectite Group_

W

Wonesite $(Na,K)(Mg,Fe,Al)_6(Si,Al)_8O_{20}(OH,F)_4$, _True Mica Group_

X

Xanthophyllite = **Clintonite**

Z

Zinnwaldite $KLiFe^{2+}Al(AlSi_3)O_{10}(F,OH)_2$, _True Mica Group_

Zussmanite $K(Fe^{2+},Mg,Mn^{2+})_{13}(Si,Al)_{18}O_{42}(OH)_{14}$, _Modulated Layer Silicate Group_

22.1 Introduction

Oxide minerals or oxides comprise the oxides, hydroxides, oxyhydroxides, and hydrated oxides of Fe, Mn, Al, Si, and Ti. They commonly occur in soils, particularly those in advanced stages of weathering where they can sometimes account for as much as 50% of the total soil mass. In the discussion to follow, a polyhedral approach will be used to introduce the mineral species and highlight their major differences and similarities (Figure 22.1). For additional structural details, the reader is referred to the literature cited. Thereafter, their occurrence and formation in soils and their influence on soil properties will be discussed, concluding with the major techniques for identifying these minerals in soils.

22.2 Iron Oxides

Iron oxide minerals are ubiquitous in soils and sediments. All of the Fe oxide minerals are strongly colored and, when finely dispersed throughout the matrix, even small amounts impart bright colors to soils. Iron oxides often cement other soil minerals into stable aggregates, and when they reach massive proportions, such cementations are called laterite or ferricrete. Because iron oxide surfaces have a strong affinity for the oxyanions of phosphorus and some transition metals, they play a significant role in the environmental cycling of these elements. A list of the Fe oxides is given in Table 22.1. Recent comprehensive reviews include Schwertmann and Taylor (1989), Cornell and Schwertmann (1996, 2003), and Bigham et al. (2002).

22.2.1 Mineral Phases

The structures of most Fe oxides can be described in terms of close-packed arrays of O and OH ions, with Fe occupying interstitial octahedral sites. Structures based on hexagonal close packing (hcp) of the anions are called α-phase, and those with cubic close packing (ccp), γ-phase (note that this convention is not necessarily followed for oxides of other elements). Both hcp and ccp structures also contain tetrahedral interstices. In two minerals, magnetite and maghemite, Fe is present in some of these tetrahedral sites as well. The basic structural unit for most of the Fe oxides, however, is an octahedron in which each Fe atom is surrounded either by six O or by both O and OH ions. The various Fe oxides differ mainly in the arrangement of these octahedra and in how they are linked.

22.2.1.1 Oxyhydroxides

Goethite (α-FeOOH) consists of double chains of edge-shared octahedra that are joined to other double chains by sharing corners and by hydrogen bonds (Figure 22.1; Cornell and Schwertmann, 1996). *Lepidocrocite* (γ-FeOOH) also contains double chains of octahedra, but they are joined by shared edges, resulting in corrugated sheets of octahedra. These corrugated sheets are stacked one on top of the other and are held together by hydrogen bonds (Figure 22.1; Ewing, 1935a, 1935b; Fasiska, 1967). *Akaganéite* (β-FeOOH) consists of double chains that share corners with adjacent chains to give a 3D structure containing tunnels 0.5 nm in cross section (Figure 22.1). These tunnels contain Cl$^-$ ions that stabilize the structure (Post and Buchwald, 1991). *Schwertmannite* ($Fe_8O_8(OH)_6(SO_4)$) is

Mn: Pyrolusite, MnO_2
     Manganite, $\gamma\text{-}MnOOH$
Ti: Rutile, TiO_2

Fe: Goethite, $\alpha\text{-}FeOOH$
Mn: Ramsdellite, MnO_2
     Groutite, $MnOOH$
Al: Diaspore, $\alpha\text{-}AlOOH$

Fe: Lepidocrocite, $\gamma\text{-}FeOOH$
Al: Boehmite, $\gamma\text{-}AlOOH$

Fe: Akaganéite, $\beta\text{-}FeOOH$
     Schwertmannite, $Fe_8O_8(OH)_6(SO_4)$
Mn: Hollandite, $Ba_x(Mn^{IV}Mn^{III})_8O_{16}$, $x = 1$
     Cryptomelane, $K_x(Mn^{IV}Mn^{III})_8O_{16}$, $x = 1.3\text{--}1.5$
     Coronadite, $Pb_x(Mn^{IV}Mn^{III})_8O_{16}$, $x = 1.0\text{--}1.4$

Mn: Romanechite, $Ba_{0.66}(Mn^{IV}Mn^{III})_5O_{10} \cdot 1.3H_2O$

Mn: Todorokite,
     $(Na,Ca,K)_{0.3\text{--}0.5}(Mn^{IV}Mn^{III})_6O_{12} \cdot 3.5H_2O$

Fe: Feroxyhyte, $\delta'\text{-}FeOOH$ (A = B = Fe)
Mn: Buserite (A = B = Mn)
     Lithiophorite, $(Li,Al)(Mn^{III},Mn^{IV})O_2(OH)_2$
     (A = Mn,Co; B = Al,Li,Ni,Cu,Zn)
     Asbolane, $(Co,Li)MnO_2(OH)_2$
     (A = Mn; B = Co,Ni)
Al: Gibbsite, bayerite, nordstrandite, $Al(OH)_3$
     (A = B = Al)

Fe: Green rust, $Fe_4^{II} Fe_2^{III}(OH)_{12}(Cl,SO_4,CO_3)$

FIGURE 22.1 **(See color insert.)** Structural schemes for oxide minerals in soils.

Mn: Chalcophanite, $ZnMn_3O_7 \cdot 3H_2O$
Birnessite, $(Na,Ca,Mn^{II}) Mn_7O_4 \cdot 2.8H_2O$

Si: α-Cristobalite, SiO_2

Fe: Hematite, $\alpha\text{-}Fe_2O_3$
Al: Corundum, $\alpha\text{-}Al_2O_3$
Ti,Fe: Ilmenite, $FeTiO_3$

Ti: Anatase, TiO_2

Fe: Magnetite, Fe_3O_4
Maghemite, $\gamma\text{-}Fe_2O_3$
Mn: Hausmannite, Mn_3O_4
Ti,Fe: Titanomagnetite, $Fe_{3-x}Ti_xO_4$
Titanomaghemite, $Fe_{2-x}Ti_xO_3$

Ti: Brookite, TiO_2

Ti,Fe: Pseudobrookite, $Fe_2^{III}TiO_5$

Ti,Fe: Pseudorutile, $Fe_2^{III}Ti_3O_8(OH)_2$

Si: α-Quartz, SiO_2
FIGURE 22.1 (continued)

TABLE 22.1 Iron Oxide Minerals: Crystallographic Properties and d Values for the Six Most Intense Diffraction Lines

Mineral	Chemical Formula	Crystal System, Space Group	Unit-Cell Dimensions (Å)	Six Most Intense Diffraction Lines d Value (Å), Relative Intensity						References[a]

isostructural with akaganéite, but instead of Cl^-, SO_4^{2-} occupies the tunnels (Figure 22.1; Bigham et al., 1990, 1994). *Feroxyhite* (δ'-FeOOH) consists of sheets of edge-sharing octahedra (Figure 22.1), with the presence of face-sharing octahedra (Manceau and Combes, 1988; Drits et al., 1993a; Manceau and Drits, 1993). In naturally occurring feroxyhite, Fe^{3+} ions are randomly distributed over the octahedral sites, while in synthetic δ-FeOOH, the Fe^{3+} ions are orderly distributed over half of the octahedral sites (Waychunas, 1991). *Ferrihydrite* ($Fe_5HO_8 \cdot 4H_2O$) is a poorly ordered Fe oxide, with a variable degree of ordering. The structure is still being investigated (Drits et al., 1993b; Manceau and Drits, 1993; Manceau and Gates, 1997) but can be visualized as a defective hematite structure containing both edge- and face-sharing octahedra (Towe and Bradley, 1967). The Fe^{3+} ions are randomly distributed over the octahedral interstices, with

many sites vacant and more OH^- and H_2O and less Fe^{3+} than in hematite (Cornell and Schwertmann, 1996).

22.2.1.2 Hydroxides

Green rusts are a group of Fe^{2+}–Fe^{3+} hydroxy salts with a structure consisting of sheets of edge-shared $Fe^{2+}(OH)_6$ octahedra in which some of the Fe^{2+} is replaced by Fe^{3+}, creating a positive layer charge. The charge is balanced by anions such as Cl^-, SO_4^{2-}, and CO_3^{2-} located between the octahedral sheets (Figure 22.1; Brindley and Bish, 1976; Taylor and McKenzie, 1980). *Bernalite*, $Fe(OH)_3 \cdot nH_2O$ (Birch et al., 1993), is a rare Fe hydroxide and has not been found in soils. *Fougerite*, $(Fe^{2+}Mg)_6 \, Fe_2^{3+}(OH)_{18} \cdot 4H_2O$, has recently been identified as a green rust mineral in soils (Trolard et al., 2007), whereas the $Fe(OH)_2$ compound has not been found as a mineral (Cornell and Schwertmann, 1996).

22.2.1.3 Oxides

Hematite (α-Fe_2O_3) consists of sheets of edge-shared octahedra with two-thirds of the available octahedral sites filled with Fe^{3+} ions. The unoccupied sites are regularly arranged to form sixfold rings of occupied octahedra analogous to dioctahedral phyllosilicate sheets (Chapter 21) and are stacked along the c-axis. Each plane of O is shared by two adjacent dioctahedral sheets. Each octahedron shares three edges with three neighboring octahedra in the same sheet and a face and six corners with nine octahedra in adjacent sheets (Figure 22.1; Blake et al., 1966; Maslen et al., 1994). *Magnetite* (Fe_3O_4), which differs from most other Fe oxides in that it contains both Fe^{2+} and Fe^{3+} ions, has an inverse spinel structure consisting of octahedral and mixed tetrahedral/octahedral layers stacked along the [111] plane, with Fe^{3+} occupying tetrahedral sites and both Fe^{2+} and Fe^{3+} in octahedral sites (Figure 22.1). *Titanomagnetites* ($Fe_{3-x}Ti_xO_4$) are solid solutions of magnetite with ulvöspinel (Fe_2TiO_4), with Ti^{4+} occupying only octahedral sites (Wechsler et al., 1984). *Maghemite* (γ-Fe_2O_3) has the chemical composition of hematite but has a structure analogous to magnetite (Figure 22.1). Most or all of the Fe occurs as Fe^{3+} and cation vacancies preserve charge balance caused by the oxidation of Fe^{2+} to Fe^{3+}. The cations are randomly distributed over the tetrahedral and octahedral sites. The vacancies are also randomly distributed but are confined to the octahedral sites. *Titanomaghemites* are oxidation products of titanomagnetites, but their structure needs clarification (Waychunas, 1991). Maghemite–magnetite solid solutions are formed by varying degrees of oxidation of magnetite.

Other metallic cations with an ionic diameter similar to Fe^{3+} (Al, Ni, Ti, Mn, Co, Cr, Cu, Zn, V) may replace the Fe ion in the structure of various Fe oxides. Isomorphous substitution of Al^{3+} for Fe^{3+} occurs most frequently and to the greatest extent (Schwertmann and Carlson, 1994). In addition to M^{3+} cations, M^{2+} and M^{4+} cations may also enter Fe^{3+} oxide structures, but the uptake is usually less than $0.1\,mol^{-1}$ (Cornell and Schwertmann, 1996).

The typical shapes of well-crystallized Fe oxide samples are listed in Table 22.2. These shapes, usually observed in samples from synthetic preparations, rocks, ferricretes, and bauxites, are frequently less well expressed by soil Fe oxides. Soil hematites usually have a granular texture, and goethites show almost no acicularity (Figure 22.2), particularly in highly weathered soils (Schwertmann and Kämpf, 1985; de Brito Galvão and Schulze, 1996). Thus, morphology alone is unreliable for distinguishing these minerals by transmission electron microscopy (TEM) (Anand and Gilkes, 1987a; Singh and Gilkes, 1992), although soil lepidocrocites often appear as thin laths, very similar to synthetic lepidocrocites (Cornell and Schwertmann, 1996). Soil Fe oxides may range from a few to several hundred nanometers in length, but data are scarce because of their tendency to occur as microaggregates (Schwertmann, 1988).

22.2.2 Occurrence and Formation

The concentration of Fe oxides in soil ranges between <1 and $>500\,g\,kg^{-1}$ and is related to parent material, degree of weathering, and pedogenic accumulation or depletion processes. Iron oxides

TABLE 22.2 Diagnostic Criteria for Iron Oxide Minerals

Mineral	Color and Munsell Hues Range	Typical Crystal Shape	DTA Events (°C)	IR Bands (cm⁻¹)	Magnetic Hyperfine Field (kOe)		
					295 K	77 K	4 K
Goethite	Strong brown to yellowish brown, 7.5YR–2.5Y	Needles, laths	Endotherm, 280–400	890, 797	382	503	506
Lepidocrocite	Reddish yellow ("orange"), 5YR–7.5YR	Laths	Endotherm, 300–350 Exotherm, 370–500	1026, 1161, 753			458
Akaganéite	Strong brown to reddish yellow, 2.5YR–7.5YR	Spindle-shaped rods					489/478/473
Schwertmannite	Reddish yellow to yellow, 5YR–10YR	Fibers	Endotherm, 100–300, 650–710 Exotherm, 540–580	3300, 1634, 1186, 1124, 1038, 976, 608			456
Ferrihydrite	Dark red to strong brown, 2.5YR–7.5YR	Spherical	Endotherm, 150				470/500
Feroxyhite	Dark red to dark reddish brown, 1.5YR–5YR	Fibers, needles	Endotherm, 250	1110, 920, 790, 670	420	530	535
Hematite	Dusky red to dark red, 5R–2.5YR	Hexagonal plates	Nil	345, 470, 540	518	542/535[a]	542/535[a]
Maghemite	Dark reddish brown, 2.5YR–5YR	Cubes	Exotherm, 600–800	400, 450, 570, 590, 630	500		526
Magnetite	Black	Cubes	[b]	400, 590	491/460[c]		

[a] With and without Morin transition, respectively.

[b] Magnetite converts via maghemite or directly to hematite, depending on particle size.

[c] For tetrahedral and octahedral Fe, respectively.
FIGURE 22.2 Transmission electron micrograph of the <0.2 μm fraction of a Rhodic Hapludox showing a goethite or hematite particle (arrow) surrounded by clean kaolinite particles. (Modified from de Brito Galvão, T.C., and D.G. Schulze. 1996. Mineralogical properties of a collapsible lateritic soil from Minas Gerais, Brazil. Soil Sci. Soc. Am. J. 60:1969–1978.)

may occur evenly distributed in the matrix or concentrated as ferricretes, layers, bands, horizons, nodules, mottles, plinthite, etc.

Iron, present as Fe^{2+} in primary minerals (mainly silicates) of most rocks, is released during weathering through protolysis and oxidation processes, hydrolyzes in contact with water, and then forms Fe^{3+} oxides. In most aerobic environments, the Fe oxides are evenly distributed resulting in homogeneous soil color. Under anaerobic conditions, however, Fe oxides may be reduced and dissolved, thus leading to a heterogeneous distribution of Fe oxides and color (redoximorphic features; Schwertmann, 1993). The formation of each of the Fe oxide minerals requires specific conditions that have been established for soils by laboratory and field observations (Schwertmann and Taylor, 1989).

In aerobic environments, goethite and hematite are the most common Fe oxides due to their high thermodynamic stability. Their formation pathway starts with Fe^{2+} released by weathering and its immediate oxidation to Fe^{3+} or by any other source of Fe^{3+} (e.g., dissolution of Fe oxides), which precipitates as ferrihydrite or goethite, depending on which of the solubility products is exceeded first (ferrihydrite, Ksp ~ 10^{-39} or goethite, 10^{-44} < Ksp < 10^{-41}). Hematite forms from its necessary precursor, ferrihydrite, through a solid-state reaction in which individual hematite crystals nucleate and grow within individual ferrihydrite aggregates by a dehydration and rearrangement process. All of the iron in each individual hematite crystal is derived from a single-ferrihydrite aggregate (Cornell and Schwertmann, 1996). The transformation of ferrihydrite to goethite, however, proceeds via a dissolution–precipitation process. The presence of face-sharing $Fe(O,OH)_6$ octahedra in ferrihydrite, as in hematite, prevents the direct solid-state transformation of ferrihydrite into goethite, which consists only of edge- and corner-sharing octahedra. Thus, the transformation of ferrihydrite to goethite requires the breakdown of the oxo-bridges of face-sharing octahedra (Combes et al., 1989). Goethite forms from Fe^{3+} ions in solution via a nucleation–crystal growth process. Hence, any Fe source (minerals, biological

exudates, organic compounds) able to keep a low Fe^{3+} activity in solution will favor goethite. Thus, the formation pathways of hematite and goethite are different but competitive.

Environmental conditions that favor the formation of ferrihydrite and its subsequent transformation to hematite are high Fe content in the parent rock (resulting in higher Fe release rate), near neutral pH (pH of minimum solubility of ferrihydrite), higher temperature or lower water activity (favoring the dehydration step) (Torrent et al., 1982), and rapid turnover of biomass (low Fe complexation) (Schwertmann, 1988). Such environmental conditions are usually related to climate (Kämpf and Schwertmann, 1983), landscape (Curi and Franzmeier, 1984; Schwertmann and Latham, 1986), landscape associated with drainage (Macedo and Bryant, 1987; da Motta and Kämpf, 1991; Peterschmitt et al., 1996; Fritsch et al., 2007), and soil depth (Bigham et al., 1978; Kämpf and Schwertmann, 1983).

In soils, the transformation rate of ferrihydrite to hematite is probably very rapid, whereas that of ferrihydrite to goethite, which proceeds through dissolution–recrystallization, is slower. This explains the widespread association of ferrihydrite–goethite, while that of ferrihydrite–hematite has been rarely found (Parfitt et al., 1988). There is no pedogenic indication for a solid-state transformation of goethite to hematite by simple dehydration, nor the inverse by simple hydration. However, high temperatures caused by forest or bush fires may transform goethite into hematite and lepidocrocite into maghemite (Stanjek, 1987; see maghemite below).

Both hematite and goethite have a similarly low solubility (Lindsay, 1979). Under moderately reducing conditions, however, a transformation of red into yellow soils (yellowing or xanthization) may take place due to a preferential dissolution of hematite over goethite (Macedo and Bryant, 1989; Jeanroy et al., 1991; Peterschmitt et al., 1996; Fritsch et al., 2005). The increased resistance of goethite to dissolution is explained by a higher Al for Fe substitution (Torrent et al., 1987; Trolard and Tardy, 1987). The solubility and dissolution of Fe oxides is reviewed by Schwertmann (1991). When Fe oxides are reduced in higher landscape positions, the soluble Fe^{2+} may be transported to lower landscape positions and reprecipitate as Fe oxides (Schwarz, 1994). In aquic environments with prolonged waterlogging, the complete removal of Fe oxides may take place, resulting in soil bleaching (chroma < 2) (da Motta and Kämpf, 1991; Peterschmitt et al., 1996). The bleached color is due to the matrix minerals (phyllosilicates, quartz, etc.) in the absence of Fe oxides.

Many species of microorganisms, mainly anaerobic bacteria, are capable of reducing Fe oxides (Lovley, 1995). As heterotrophic organisms, they depend on available biomass for metabolic oxidation so that reduction in soils is most intense in the upper horizons. The process usually involves enzymatic transfer of electrons by microorganisms from the decomposing biomass to Fe^{3+} (Ghiorse and Ehrlich, 1992; Lovley, 1992, 1995).

Some Fe and Mn oxides may be formed by microorganisms in a biologically induced form outside the cell, or matrix mediated, by internal cellular precipitation (Ghiorse and Ehrlich, 1992). The most common occurrence of biotic formation of

Fe oxides is Fe ochre in field drains (Houot and Berthelin, 1992), the Fe plaque in the root zone of wetland plants (Weiss et al., 2003), and the Fe precipitate, yellow boy, in acid mine drainages (Bigham et al., 1992). Aspects of biomineralization of Fe and Mn in soils are reviewed in Skinner and Fitzpatrick (1992).

The typical Fe oxides of seasonally reduced soil environments are goethite, lepidocrocite, and ferrihydrite, formed by abiotic or biotic processes. Therefore, goethite and lepidocrocite are widely associated in reductomorphic soils, whereas hematite is restricted to mottles and nodules (Schwertmann and Kämpf, 1983; Fitzpatrick et al., 1985; Wang et al., 1993; dos Anjos et al., 1995). While goethite can form from either Fe^{2+} or Fe^{3+} ions in solution, lepidocrocite in soils seems to require the presence of Fe^{2+} ions (Schwertmann and Taylor, 1989). Thus, lepidocrocite, recognized by its bright orange color, indicates prevailing reductomorphic conditions in a soil profile leading to the formation of Fe^{2+}. Factors that favor the formation of goethite over lepidocrocite, however, are a higher partial pressure of CO_2, normally found closer to roots, the presence of HCO_3^- or CO_3^{2-}, an increasing rate of oxidation, and the presence of Al in the system (Schwertmann and Taylor, 1989; Carlson and Schwertmann, 1990).

Ferrihydrite has been reported in ochreous precipitates from the oxidation of emerging, Fe^{2+}-containing waters (Schwertmann and Fischer, 1973; Carlson and Schwertmann, 1981; Schwertmann and Kämpf, 1983), in bog and lake Fe ores (Schwertmann et al., 1982), in podzol B horizons (Adams and Kassim, 1984), in placic horizons (Campbell and Schwertmann, 1984), in Andepts (Parfitt et al., 1988), in soil iron pans (Childs et al., 1990), and in constructed wetlands for acid drainage treatment (Karathanasis and Thompson, 1995). These occurrences reflect an environment where Fe^{2+} is rapidly oxidized (abiotically or biotically) in the presence of high concentrations of organic matter and/or Si. These compounds and possibly others hinder the immediate formation of FeOOH phases and the subsequent transformation of ferrihydrite to more stable Fe oxides (Schwertmann, 1966; Cornell, 1987). In contrast, in tropical soils, the concentration of ferrihydrite is very low because of low interference of Si and organics. The presence of ferrihydrite together with FeOOH phases may indicate that environmental conditions are not favorable for crystal development or that the formations are relatively young, as in paddy soils (Wang et al., 1993) and constructed wetlands (Karathanasis and Thompson, 1995).

Reductomorphic soils often display greenish-blue colors that change rapidly to yellowish brown on exposure to the air. These colors are indicative of the presence of green rusts, recently identified as fougerite (Trolard et al., 2007). Iron-reducing bacteria appear as the main factor involved in green rust formation (Berthelin et al., 2006). Green rusts occur under reducing and weakly acid to weakly alkaline conditions as intermediate phases in the abiotic formation of goethite, lepidocrocite, and magnetite (Schwertmann and Fechter, 1994).

Schwertmannite has been found in strongly acid, sulfate-rich waters associated with mining activities (Bigham et al., 1990, 1992, 1994, 1996b; Fanning et al., 1993), a Histosol that received runoff from lead smelting activities (Gao and Schulze,

2010a, 2010b), and in an acid alpine stream draining a pyritic schist (Schwertmann et al., 1995a). Most of these occurrences reflect acid environments where bacteria catalyze the oxidation of FeS_2 releasing Fe^{3+} and SO_4^{2-} that, in the pH range 2.8–4.0, precipitate as schwertmannite (Bigham et al., 1992, 1996b). At lower pH, jarosite is favored, while at higher pH values, goethite and ferrihydrite form (Bigham et al., 1996a). Schwertmannite is metastable and converts to goethite over time. Bigham et al. (1992) proposed a biogeochemical model for the precipitation of jarosite, schwertmannite, and ferrihydrite, and their conversion to goethite. The model considers the oxidation of Fe^{2+} by *Thiobacillus ferrooxidans* or oxygen, the concentration of SO_4^{2-}, the pH, and the presence of other cations (K, Na) in the system.

Magnetite in soils is usually inherited from the parent rock (lithogenic), but both biologically (Fassbinder et al., 1990) and abiotically formed magnetite (Maher and Taylor, 1988) has been reported. The alteration of magnetite to hematite via solid-state transformation, with no evidence for maghemite development, is described by Gilkes and Suddhiprakarn (1979) and Anand and Gilkes (1984a). In laboratory studies, particle size determines whether hematite or maghemite forms when magnetite is oxidized below 220°C (Egger and Feitknecht, 1962; Gallagher et al., 1968). Particles less than 300 nm in diameter transform to maghemite, while larger particles oxidize to hematite. This may explain why soil maghemites typically occur in the clay fraction.

Maghemite is common in many different soils, especially in the tropics and subtropics, occurring dispersed or concentrated in concretions (Taylor and Schwertmann, 1974; Curi and Franzmeier, 1984; Anand and Gilkes, 1987a; Fontes and Weed, 1991). The two major possible pathways for maghemite formation in soils are the aerial oxidation of lithogenic magnetite (Fontes and Weed, 1991) and the transformation of other pedogenic Fe oxides by heating (between 300°C and 425°C) in the presence of organic compounds (Schwertmann and Fechter, 1984; Anand and Gilkes, 1987b; Stanjek, 1987).

Akaganéite and feroxyhite are both rare minerals. Akaganéite has been found in environments with high chloride concentrations (e.g., 0.1 M), low pH (e.g., 3–4), and high temperature (e.g., 60°C), as found in some hot springs and volcanic deposits (Schwertmann and Fitzpatrick, 1992) and has only recently been reported in soils (Fitzpatrick et al., 2008; Gao and Schulze, 2010a, 2010b). Laboratory synthesis showed that chloride is essential for the crystallization of akaganéite (Shah Singh and Kodama, 1994). The mechanism of feroxyhite formation in nature is unknown. It has been observed in rusty precipitates, formed in the interstices of sand grains from rapidly flowing Fe^{2+}-containing water, which was quickly oxidized (Carlson and Schwertmann, 1980). A possible association with dominant ferrihydrite in some typic Hydrandepts of Hawaii is reported by Parfitt et al. (1988). The similarity of the x-ray diffraction (XRD) patterns of feroxyhite and ferrihydrite makes it extremely difficult, however, to distinguish these minerals in natural samples (Carlson and Schwertmann, 1981).

The different types of Fe oxides may show a partial replacement of Fe by other cations. This substitution is conditioned

by the availability of cations that, in turn, makes it representative of specific environments of the Fe oxide formation, like a mineralogical–pedochemical signature. So far, such relationships have been established for Al substitution in goethites and for V^{3+} in goethite and hematite (Schwertmann and Pfab, 1994, 1996). Medium to high Al substitution (0.15–0.33 mol fraction) is usually observed in goethites from environments with low Si and high Al activity, found in highly weathered tropical and subtropical soils, bauxites, and saprolites (Fitzpatrick and Schwertmann, 1982; Curi and Franzmeier, 1984; Schwertmann and Kämpf, 1985; Anand and Gilkes, 1987a; Fontes et al., 1991; Singh and Gilkes, 1992; Muggler, 1998), whereas goethite with low substitution (0–0.15 mol fraction) prevails in slightly acidic, eutrophic soils and in redoximorphic soils (Fitzpatrick and Schwertmann, 1982). The occurrence of goethites with highly contrasting Al substitution indicates changes in the weathering rate or soil redox conditions (da Motta and Kämpf, 1991; Muggler, 1998). The presence of V^{3+} in goethite and hematite may be used as an indicator for former anoxic environments (Schwertmann and Pfab, 1996).

22.2.3 Influence on Soil Properties

Crystals of Fe oxides in soils are often extremely small, sometimes as small as 5 nm in diameter for poorly crystalline minerals like ferrihydrite or as small as 150 nm in diameter for better crystalline minerals like goethite and hematite. Structural disorder is common. Fe oxides, therefore, exhibit a large specific surface area (70–250 $m^2\,g^{-1}$). They usually occur in higher amounts in comparison to Mn and Al oxides, they have a high point of zero charge (PZC; pH 7–9) and a pH-dependent surface charge. All these factors explain the substantial influence of Fe oxides on the physical and chemical properties of soils.

Significant correlations have been found between the sorption of heavy metals (Cu, Pb, Zn, Cd, Co, Ni, Mn), anions (PO_4, SO_3, MoO_4, AsO_4, Se_4O, S_4O, and organic anions), and the content and mineralogy of Fe oxides (Chapter 17).

The Munsell color ranges for the various Fe oxides are listed in Table 22.2. Detailed aspects of that subject are reviewed by Schwertmann (1993) and Cornell and Schwertmann (1996). The iron oxides may show a variation of color with their crystal size and the isomorphous substitution of Fe by foreign ions (Schwertmann, 1993). Basically, reddish soil color (Munsell hues 5YR and redder) is due to the presence of hematite (and maghemite in some tropical soils), masking the presence of goethite. Thus, the hematite content determines the redness of a soil (Torrent et al., 1983), while the yellow color due to goethite (Munsell hue between 7.5YR and 2.5Y) is expressed only in the absence of hematite. The presence of lepidocrocite is indicated by an orange color, normally restricted to mottles or localized spots in aquic environments. In surface soils, the colors due to Fe oxides may be masked by black organic compounds. Information about aeration and soil drainage can be inferred from the distribution or absence of different Fe oxide minerals in soils, according to their specific formation conditions described above.

Landscape sequences of red soils (hematite and goethite) on well-drained hilltops, through yellow soils (goethite) on moderately drained midslopes, to mottled and gray soils in poorly drained valleys are examples of Fe oxides acting as indicators of aerobic and anaerobic environments (Peterschmitt et al., 1996). Localized accumulations of Fe oxides (mottling, plinthite) and bleached matrix colors (chroma < 2), indicative of seasonal to permanent waterlogged soil environments, are used as diagnostic criteria for redoximorphic features and aquic regimes (Chapter 2).

The aggregating effect of Fe oxides in soils is indicated by significant correlations between the fraction of water-stable aggregates or related structural properties, and the content of Fe oxides (see Schwertmann and Taylor, 1989; Barthès et al., 2008), by electron microscopy (EM) observations of Fe oxide deposits on kaolinite platelets (Fordham and Norrish, 1979), and by the dispersion of aggregated soils after removal of their Fe oxides with a reducing agent (McNeal et al., 1968). Although an aggregating effect of the Fe oxides in soils is generally accepted, the exact mechanism remains obscure. Thin sections and scanning electron microscopy (SEM) observations of nodules, concretions, and ferricretes suggest that cementation develops through the growth of Fe oxide crystals in place between matrix particles, leading to a very stable, nondispersible association of matrix particles (Shafdan et al., 1985). Aggregates, on the other hand, seem to form through an attraction between positively charged Fe oxide particles and negatively charged matrix particles, mainly clay-sized phyllosilicates. A typical example of aggregation is the highly stable microaggregates (coffee powder structure) found in Oxisols. Because these aggregates are not dispersible in water, they have a significant influence on the water-holding capacity and the hydraulic conductivity of these soils (van Wambeke, 1992). On the other hand, these aggregates can be dispersed by organic ligands (oxalate, citrate) without solubilizing much iron (Pinheiro-Dick and Schwertmann, 1996).

22.2.4 Identification

22.2.4.1 Field Techniques

Fe oxides show striking colors, ranging between yellow and red. Particular colors are typical of the various forms and are helpful for their identification in the field (Table 22.2). Correlations have been established between Munsell hue and a redness or yellowness index based on hematite/goethite ratios and hematite content in soils (Torrent et al., 1983). Color alone is, however, not sufficient to unequivocally identify specific Fe oxide minerals. The presence of the magnetic Fe oxides, magnetite, and maghemite, can be easily detected in soils with a hand magnet (Schulze, 1988).

22.2.4.2 Chemical Dissolution Techniques

Chemical dissolution procedures for Fe oxides, initially proposed to eliminate their interference in the examination of phyllosilicates, were later developed to dissolve, and thus

to quantify, specific phases (see reviews by Borggaard, 1988; Parfitt and Childs, 1988). However, the identity of the dissolved phases must be determined by noninvasive techniques, such as XRD and Mössbauer spectroscopy. Potassium or Na pyrophosphate solutions have been used for estimating Fe (and Al) organic complexes (McKeague, 1967; Bascomb, 1968). The soil is usually shaken for 16 h with 0.1 M pyrophosphate at pH 10, but the extraction and clarification procedures are highly technique dependent (Schuppli et al., 1983; Loveland and Digby, 1984). For the extraction of short-range order Fe oxides (predominantly ferrihydrite), a 2 (Schwertmann, 1964) or 4 h (McKeague and Day, 1966) extraction with 0.2 M ammonium oxalate at pH 3 in the dark is widely used. This technique also extracts Fe from organic complexes and poorly crystalline lepidocrocite (Ohta et al., 1993), whereas some magnetites are partly dissolved. Feroxyhite is more resistant to the 2 h oxalate treatment than ferrihydrite (Carlson and Schwertmann, 1980), and for schwertmannite, a 15 min treatment is used (Murad et al., 1994; Bigham et al., 1996b). According to Wang et al. (1993), a shorter oxalate treatment (~10–30 min) is more appropriate to measure ferrihydrite in <2 μm reductomorphic soil fractions than the much longer treatments commonly used for soils. For the complete dissolution of the pedogenic Fe oxide minerals, without dissolution of other minerals, a treatment with sodium dithionite–citrate–bicarbonate (DCB) is used. The extraction is carried out for 15 min at 75°C (Mehra and Jackson, 1960) or by shaking for 16 h with a dithionite–citrate solution at room temperature (Holmgren, 1967). However, as dissolution is affected by particle size, crystallinity (particularly for lithogenic magnetite and hematite) and high Al substitution (goethite and hematite), several DCB treatments may be required.

The ratio of oxalate-extractable Fe (Fe_o) to DCB-extractable Fe (Fe_d) quantifies the proportion of the more and less active fractions, respectively. A high Fe_o/Fe_d ratio and a loss in redness after oxalate treatment give first indication of ferrihydrite in a sample. Additionally, it is a useful parameter for characterizing soil properties (e.g., P sorption) and pedogenic processes (McKeague and Day, 1966; Blume and Schwertmann, 1969). The ratio of Fe_d to Fe_t (total Fe content by HCl or HF digestion) quantifies the proportion of Fe in primary silicate minerals, which has been released by weathering and precipitated as Fe^{3+} oxides, hence estimating Fe sources for potential Fe oxide formation and/or soil weathering stage. Advanced soil weathering stages, indicated by Fe_d/Fe_t ratios > 0.8, are usually shown by Oxisols and Ultisols.

A field test for the presence of Fe^{2+} ions and ferric-organic complexes in reductomorphic soils can be performed with a solution of α,α'-dipyridil (Childs, 1981; Kennedy et al., 1982) or with a solution of 1:10-phenanthroline (Richardson and Hole, 1979). Lovley and Phillips (1987) proposed the use of hydroxylamine hydrochloride to determine whether Fe^{3+} is available for microbial reduction. The amount of reducible Fe in natural wetlands and rice paddies is highly correlated to the labile and stable Fe^{3+} oxides (van Bodegom et al., 2003).

22.2.4.3 X-Ray Diffraction and Other Spectroscopic Techniques

The identification of the various Fe oxides requires physical methods, like XRD, differential thermal analysis (DTA), infrared spectroscopy (IR) (Cambier, 1986), Mössbauer spectroscopy (Murad, 1988, 1996), electron microscopy (EM) (Boudeulle and Muller, 1988; Eggleton, 1988), or magnetic measurements (Coey, 1988). A review of characterization methods for Fe oxides is given by Cornell and Schwertmann (1996) and Schwertmann and Taylor (1989). The most important diagnostic criteria are summarized in Tables 22.1 and 22.2. XRD patterns for the major soil Fe oxides are shown in Figure 22.3.

For powder XRD, unless one uses a monochromator, CoKα or FeKα radiation should be employed to avoid the high-fluorescence background that results when Fe-rich samples are irradiated with CuKα radiation. The sensitivity of XRD is improved by using a differential XRD method (Schulze, 1981) and selective dissolution treatments (Wang et al., 1993). Due to the low concentration of Fe oxides in soils, concentration techniques may be necessary (Schulze, 1988), like particle-size separation, magnetic separation (Schulze and Dixon, 1979), and, for goethite and hematite in kaolinitic soils, a 5 M NaOH treatment (Norrish and Taylor, 1961; Kämpf and Schwertmann, 1982a). A quantitative determination of Fe oxide minerals in soils is generally possible using the intensities of selected x-ray lines, DTA peaks, or Mössbauer hyperfine sextets. Suitable standards with the same characteristics may be isolated from soils or can be synthesized. The accuracy of the quantification can be controlled by comparison with the chemically determined total amount of Fe oxides (Fe_d) (Kämpf and Schwertmann, 1982b).

The Al substitution in goethite can be calculated from the unit-cell c-dimension by Al (mole fraction) = 17.30−57.20c (nm) (Schulze, 1984). The c value is obtained from the XRD positions d(110) and d(111) by $c = [1/d(111)^2 − 1/d(110)^2]^{-1/2}$, with all goethite data based on space group *Pbnm* (Table 22.1). In hematite, Al substitution is given by Al (mole fraction) = 31.09−61.71a (nm), where a = d(110)2, or, preferably, a = d(300)2√3 (Schwertmann et al., 1979).

22.3 Manganese Oxides

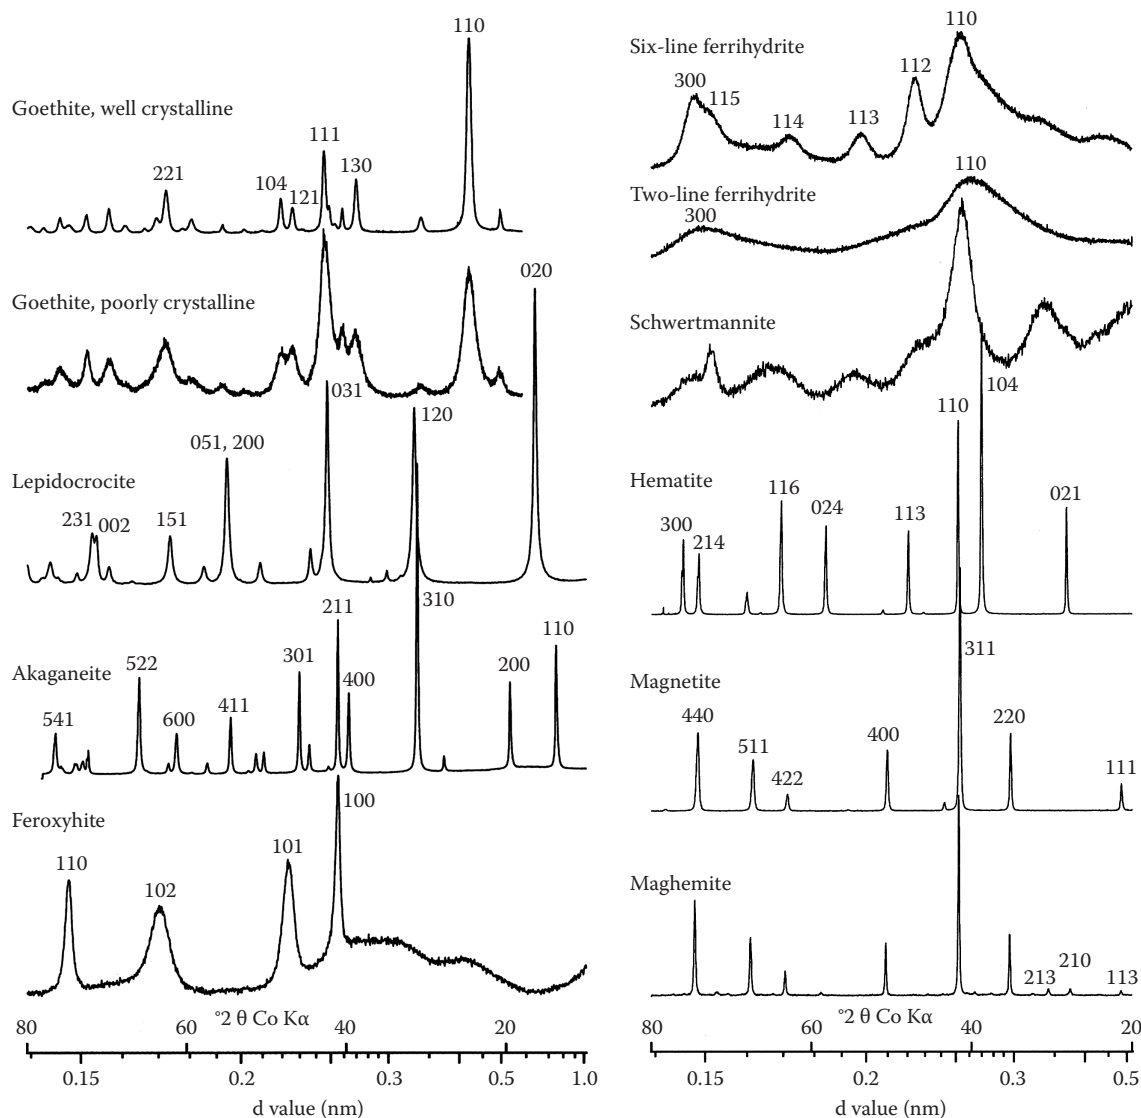
Manganese oxides are usually minor components in soils but with a significant influence on the soil chemical properties. While Mn is a micronutrient essential for plants and animals, it is the only plant essential element that also frequently occurs in toxic concentration in acid soils. The mineralogy of Mn oxides is complicated by the large number of minerals and the lack of precise knowledge of some of their structures, leading to uncertainties as to whether certain forms should be regarded as distinct mineral species, or merely as variants, or mixtures of other mineral forms (McKenzie, 1989; Post, 1992). The poor crystallinity and low concentration of these minerals in most soils is a further challenge for their characterization. A list of Mn oxides is given in Table 22.3. More information can be found in McKenzie (1989), Graham et al. (1988), and Dixon and White (2002).


FIGURE 22.3 XRD patterns for the major soil iron oxide minerals (Co Kα, peaks are labeled with their Miller indices). (From Cornell, R.M., and U. Schwertmann. 1996. The iron oxides. Wiley-VCH Verlag, Weinheim, Germany.)

22.3.1 Mineral Phases

Manganese oxides consist mainly of Mn in octahedral coordination. The various minerals differ in the arrangement and linkage of the octahedra. The Mn oxides may be placed into three groups: (1) Tectomanganates or tunnel structures, (2) phyllomanganates or layer structures, both groups with mainly tetravalent Mn, and (3) the trivalent oxides or lower oxides.

22.3.1.1 Tectomanganates (Tunnel Structures)

Tectomanganates are formed from single, double, or wider chains of MnO_6 octahedra that are linked into a framework, thus forming tunnels (or channels) through the structures. These tunnels are occupied by large foreign cations and water molecules. Pyrolusite, ramsdellite, and nsutite are also referred

as chain structures because they do not contain tunnels but are included in the group of tectomanganates because of their structural similarity to the channel or tunnel structure members.

Pyrolusite, MnO_2, consists of single chains of edge-sharing MnO_6 octahedra linked by sharing corners to form 1×1 pseudotunnels (Figure 22.1; Baur, 1976). The single rows of unoccupied octahedral sites are not wide enough to accommodate foreign ions or water molecules. High-resolution transmission electron microscopy (HRTEM) of pyrolusite crystals showed lamellae with the structure of ramsdellite (Yamada et al., 1986). *Ramsdellite*, MnO_2, consists of double chains of MnO_6 octahedra forming 1×2 tunnels (Figure 22.1; Post, 1992), that possibly contain water molecules (Potter and Rossman, 1979). *Nsutite* has a structure formed by the intergrowth of pyrolusite-like single chains and ramsdellite-like double chains of octahedra

TABLE 22.3   Manganese Oxide Minerals: Crystallographic Properties and d Values for the Six Most Intense Diffraction Lines

[a] Designation commonly used in the literature for a synthetic compound with the same crystal structure as the natural mineral are given in parentheses.

[b] Numbers of the format XX-XXXX indicate ICDD file number (ICDD, 1994).

in random fashion (Zwicker et al., 1962; Potter and Rossman, 1979; Turner and Buseck, 1983). Inclusions of todorokite have also been found in nsutite (Turner and Buseck, 1983). *Hollandite*, *cryptomelane*, and *coronadite*, sometimes grouped as α-MnO_2, consist of double chains of edge-sharing MnO_6 octahedra linked to form 2 × 2 tunnels (Figure 22.1; Post et al., 1982; Post and Burnham, 1986; Post and Bish, 1989). These minerals have the general formula $A_{0-2}(Mn^{4+},Mn^{3+})_8(O,OH)_{16}$. The tunnels contain water molecules along with the A cation, which is primarily Ba^{2+} in hollandite, K^+ in cryptomelane, and Pb^{2+} in coronadite. Natural samples usually contain a variety of cations in the tunnels. These large cations are located at specific tunnel sites, and their presence is necessary to prevent the structure from collapsing (Giovanoli, 1985a). The charges of the tunnel cations are balanced by the substitution of Mn^{4+} by Mn^{3+} ions. *Romanèchite* consists of double and triple chains of edge-sharing octahedra that share corners to form a framework containing 2 × 3 tunnels. The tunnels contain Ba^{2+} (and a variety of other large cations, such as Na, K, Sr) and water molecules (Figure 22.1; Turner and Post, 1988). The charges of the tunnel cations are balanced by the substitution of Mn^{4+} by Mn^{3+} ions. HRTEM images show that intergrowths of romanèchite and hollandite are common and are produced by the sharing of the double chains common to both minerals with double or triple chains occurring at random (Turner and Buseck, 1979). While romanèchite has also been called psilomelane, McKenzie (1989) used psilomelane for a structural type and Waychunas (1991) for mixtures of Mn oxide minerals. *Todorokite*, which had its structure and existence as a single mineral questioned until recently (Burns et al., 1985; Giovanoli, 1985b), consists of triple chains of edge-sharing MnO_6 octahedra linked to form large 3 × 3 tunnels (Post and Bish, 1988) containing Na, Ca, K, Ba, Sr, and water molecules (Figure 22.1). The octahedra at the edges of the triple chains are larger than those in the middle and, therefore, probably accommodate the larger, lower-valence cations (Mg^{2+}, Mn^{3+}, Cu^{2+}, Ni^{2+}, etc.) found in todorokite samples (Post and Bish, 1988). The occurrence of variable tunnel widths (3 × 2, 3 × 3, 3 × 4, and 3 × 5) observed in HRTEM images suggests that todorokite represents a family rather than a single mineral (Turner and Buseck, 1981).

22.3.1.2 Phyllomanganates (Layer Structures)

Chalcophanite has a layer structure composed of sheets of edge-sharing MnO_6 octahedra alternating with planes of Zn cations (but also Mn^{2+}, Ba, Ca, Mg, K, Pb, Cu, etc.) and water molecules (Figure 22.1; Ostwald, 1985; Post and Appleman, 1988). One of every seven octahedral sites in the Mn–O sheet is vacant, and the Zn cations are situated above and below the vacancies. The other phyllomanganates are structurally analogous to chalcophanite, with Na^+, Ca^{2+}, K^+, and Mn^{2+} as interlayer cations. *Birnessite*, consists of a layer structure analogous to chalcophanite but with fewer vacancies in the octahedral sheets and with Na, K, or Mg replacing the Zn cations (Figure 22.1; Post and Veblen, 1990). The interlayer region contains water molecules as in chalcophanite. *Rancieite* has a layer

structure similar to birnessite, with Ca^{2+} as the main interlayer cation and interlayer water molecules (Bardossy and Brindley, 1978; Potter and Rossman, 1979; Chukhrov et al., 1980). The structure and existence in nature of *buserite*, also known as 10 Å manganite, are still unresolved. Buserite appears to have a layer structure similar to birnessite, with the larger, 10 Å layer spacing probably due to interlayer water (Waychunas, 1991). *Lithiophorite* has a layer structure comprising sheets of edge and corner-sharing MnO_6 octahedra alternating with sheets of $(Al,Li)(OH)_6$ octahedra (Figure 22.1; Post and Appleman, 1994). The cation sites in the Mn–O octahedral sheet are fully occupied, 2/3 with Mn^{4+} and 1/3 with Mn^{3+}. In the (Al,Li)–OH octahedral sheet, 2/3 of the sites are occupied by Al and 1/3 by Li cations. Lithiophorites with only traces of Li and others with wide variations in Ni, Co, Cu, and Zn concentrations inversely related to the Al content have been found (Ostwald, 1984a). According to Manceau et al. (1987, 1990), Co can occur within the octahedral Mn sheets, while Ni and Cu are located in the (Al,Li)–OH octahedral sheet, probably replacing Li, whereas in asbolane, Ni builds partial $Ni(OH)_2$ sheets. Manceau et al. (1987) also found evidence for mixed layering between lithiophorite and asbolane, as observed by Ostwald (1984a). *Asbolane* has a layer structure with alternating sheets of Mn^{4+}–O octahedra and Co–Ni–OH octahedra (Figure 22.1; Chukhrov and Gorshkov, 1981). The Co–Ni sheet may be discontinuous (island-like). The positive charge of the Mn^{4+} sheets is balanced by the negative charge of the Co–Ni sheets. Hydrogen bonding occurs between the oxygen atoms of the Mn sheets and the hydroxyl groups of the Co–Ni sheets. Most asbolanes are fine-grained, poorly crystalline minerals. *Vernadite* has been considered a disordered birnessite, lacking regular stacking in the c-axis. However, according to Chukhrov et al. (1980) and Chukhrov and Gorshkov (1981), it is a distinct mineral species with a disordered structure that has some similarity to that of birnessite, represented by layers of hexagonal close-packed O and water molecules in which less than half of the octahedra are occupied by Mn ions. Diffraction patterns of vernadite have only two d-spacings at ~2.4 and ~1.4 Å, whereas birnessite yields additional reflections at 7.0–7.2, 3.5–3.6 Å, and other spacings (Chukhrov et al., 1980).

22.3.1.3 Trivalent Manganese Oxides and Oxyhydroxides

Groutite (α-MnOOH) is isostructural with goethite and ramsdellite (Figure 22.1; Glasser and Ingram, 1968). *Feitknechtite* (β-MnOOH) has a structure similar to lepidocrocite (Figure 22.1), but its structure has not been refined (Waychunas, 1991). *Manganite* (γ-MnOOH) is similar to pyrolusite and rutile (Figure 22.1; Huebner, 1976). *Hausmannite* (Mn_3O_4) has a disordered spinel structure analogous to magnetite (Figure 22.1; Huebner, 1976). *Manganosite* has the NaCl structure and is of limited occurrence in nature (Huebner, 1976). *Bixbyite* (α-$(Fe,Mn)_2O_3$) has an anion-deficient fluorite structure (Geller, 1971), while pure (synthetic) α-Mn_2O_3 is orthorhombic (Huebner, 1976; Waychunas, 1991).

22.3.2 Occurrence and Formation

Many studies have been made on the synthesis of Mn oxides (McKenzie, 1971; Hem and Lind, 1983; Giovanoli, 1985a) and the transformation of one form to another (Faulring et al., 1960; Bricker, 1965; Glasser and Smith, 1968; Rask and Buseck, 1986). Some of these studies, even if more applicable to diagenetic and hydrothermal conditions and to the formation of ore deposits, may be extrapolated to soil environments. Of the variety of Mn oxides found in terrestrial environments, only a few have been positively identified in soils. For example, nsutite and pyrolusite are common in Mn ore deposits (Zwicker et al., 1962; Varentsov, 1982) but have not been found in soils. Synthesis studies show that large amounts of foreign ions prevent the formation of nsutite, while even small amounts of foreign ions prevent the formation of pyrolusite. In soils, the foreign ions released by mineral weathering probably limit the formation of these Mn oxides, whereas in ore deposits, the abundance of Mn would aid in the removal of foreign ions, thus allowing the formation of nsutite and pyrolusite (McKenzie, 1989). According to Ostwald (1984b), the mineral associations birnessite–montmorillonite, chalcophanite–kaolinite, and lithiophorite–gibbsite observed in Australian Mn ore deposits may represent special cases of metasomatic replacements of clay minerals by phyllomanganate minerals, whereas the occurrence of vernadite in a wide range of substrates is explained by its formation as a product of rapid microbial oxidation of Mn^{2+} (Chukhrov and Gorshkov, 1981).

Laboratory experiments show that Mn_3O_4 (hausmannite) is the initial product of the chemical oxidation of aqueous Mn^{2+} at 25°C in moderately alkaline solutions (pH 8.5–9.5). It converts to β-MnOOH (feitknechtite) and then to γ-MnOOH (manganite) by aging in solution (Hem and Lind, 1983; Murray et al., 1985). At 0°C, the initial product is feitknechtite, which converts to MnO_2, identified as ramsdellite or birnessite (Hem and Lind, 1983). The formation and transformation of Mn oxides through successively increasing oxidation states are compatible with the common distribution of Mn oxides observed in supergene Mn ores (Bricker, 1965) and in lateritic weathering sequences (Parc et al., 1989). Minor inversions of that Mn oxidation sequence occur, however, due to the presence of foreign ions, thus promoting the formation of cryptomelane and lithiophorite instead of pyrolusite (Parc et al., 1989). The influence of microorganisms and organic compounds additionally increases the complexity of Mn oxide formation in soil environments.

Manganese is one of the first elements released during weathering of primary minerals, which explains its common accumulation in saprolites. Mobile in solution as Mn^{2+}, its oxidation to Mn^{3+} and Mn^{4+} and its subsequent precipitation is often accelerated by microorganisms (Ghiorse, 1988). Most of the Mn oxides found in surface environments are compounds of Mn^{4+} with some Mn^{3+}. The typical fine-grain size and poor crystallinity of the Mn oxides in soils are probably related to seasonal moisture changes, the presence of interfering organic and inorganic components in the soil solution, and the presence of multiple Mn oxidation states.
FIGURE 22.4 Scanning electron micrograph of the fractured surface of a nodule from a Tropeptic Eutrustox showing crystals of the Mn oxide mineral lithiophorite. (From Golden, D.C., J.B. Dixon, and Y. Kanehiro. 1993. The manganese oxide mineral, lithiophorite, in an Oxisol from Hawaii. Aust. J. Soil Res. 31:51–66.)

Manganese oxides are commonly of authigenic origin in soils, formed by direct chemical or biochemical precipitation from solution and by crystallization of poorly organized colloidal sols. However, little is known about the processes involved in their pedogenic formation. In most soils, Mn oxides occur as finely dispersed particles but may also be found as discontinuous black–brown coatings of ped surfaces (mangans), as pore fillings, and as concretions and nodules (Figure 22.4). Their presence and concentration are more likely in soil environments with alternate reducing and oxidizing conditions, which affect the mobility and the precipitation of Mn (White and Dixon, 1996). Thus, higher accumulations of Mn oxides are more frequent in soils with restricted drainage such as the aquic suborders (Aqualfs, Aquolls, Aquults, etc.), and intergrades (Aquic Hapludalfs, Aquic Dystrochrepts, etc.), and are also commonly found in saprolites. However, Mn accumulations in a soil are not necessarily an indication of a present redox environment but may reflect former wetter conditions (Allen and Hajek, 1989).

Mn and Fe oxides are usually associated in nodules with dominant silicates (quartz, clay minerals) that probably act as primary templates for the Mn and Fe oxidation and precipitation (Schwertmann and Fanning, 1976). Golden et al. (1986) demonstrated experimentally that Mn^{4+} oxide minerals can also act as oxidizing agents of Fe^{2+} ions in solution, causing the precipitation of Fe^{3+} oxides in association with Mn oxides. The crystal growth and progressive cementation of the nodules can be explained by an autocatalytic oxidation of Mn^{2+} adsorbed onto the formed Mn (and Fe) oxides (McBride, 1994). Thus, abiotic oxidation accelerates in response to the increased surface available for selective adsorption of Mn^{2+}. The overall process, of Mn oxidation and nodule formation, may also be promoted by Mn-oxidizing bacteria (Robbins et al., 1992; Ehrlich, 1996; Leinemann et al., 1997) and fungi (Thompson et al., 2005, 2006). Furthermore, microorganisms may indirectly control local environments, through elevation of pH and Eh, which favor

oxidation of Fe and Mn (Ghiorse and Ehrlich, 1992). Models of biotic oxidation of Mn (and Fe) are described by Ghiorse and Ehrlich (1992), Ehrlich (1990), and Tebo et al. (2004).

In soil samples from Australia, the abundance of Mn oxides decreased from birnessite and lithiophorite, over hollandite, to only one occurrence of each of pyrolusite and todorokite (Taylor et al., 1964). A high frequency of birnessite was also found in soils of other regions (Taylor, 1968; Ross et al., 1976). Todorokite formation from Mn released by the weathering of Mn-substituted siderite in lignite overburden was reported by Senkayi et al. (1986). Birnessite, lithiophorite, and lattice fringes attributed to todorokite were observed in nodules of a Vertic Argiustoll, while lithiophorite only was found in a Rhodic Paleudult (Uzochukwu and Dixon, 1986). Romanèchite was identified in nodules of a Typic Ochraquult (Robbins et al., 1992), and vernadite associated with feroxyhite was identified in a Scottish Gleyic Cambisol (Birnie and Paterson, 1991). Chukhrov and Gorshkov (1981), as cited by McKenzie (1989), reported that the most common Mn oxide in soils was vernadite, followed by birnessite, cryptomelane, todorokite, and hausmannite. Chukhrov and Gorshkov (1981) reported the presence of hausmannite in unspecified soils with pH ~ 8.2.

22.3.3 Influence on Soil Properties

The wide range of PZC values reported for synthetic samples of Mn oxides (Healy et al., 1966; Crowther and Dillard, 1983; Oscarson et al., 1983), from 1.5–3.5 for birnessite to 2.8–4.6 for the hollandite group and 6.4–7.3 for pyrolusite, is probably related to the synthesis conditions. In general, most Mn oxides have a PZC at a pH < 4.0, a high negative charge, a large range of surface area (5–$360\,m^2\,g^{-1}$), and show a strong specific adsorption of cations.

A high sorption capacity of Mn oxides for metal ions has been found by many authors (see Murray, 1975; McKenzie, 1989). In general, metal ions are sorbed in the increasing order Mg < Ca < Sr < Ba < Ni < Zn < Co < Mn < Cu < Pb (Murray, 1975), leading to the accumulation of relatively high concentrations of heavy metals (Childs, 1975; Sidhu et al., 1977) and actinides in the Mn oxides (Means et al., 1978; Cerling and Turner, 1982).

Manganese oxides are strong inorganic oxidants, thus affecting the availability or the hazard of particular metals. In the case of Co adsorption onto the birnessite surface at pH <7, Co^{2+} is oxidized to Co^{3+} by Mn^{4+}, with formation of Mn^{2+} in the process (Crowther and Dillard, 1983). The strong adsorption mechanism has a significant influence on the availability of Co to plants (Adams et al., 1969; McKenzie, 1978).

The Mn oxides have a major influence on the toxicity and bioavailability of As and Cr in terrestrial and aquatic environments. The reduced species As^{3+}, which is more toxic, more soluble, and more mobile than the oxidized As^{5+} species, is effectively adsorbed and oxidized by Mn^{4+} oxides at pH <6 (Oscarson et al., 1983; Thanabalasingam and Pickering, 1986; Scott and Morgan, 1995). However, the ability to deplete the concentration of As^{3+} in solution varies between different types of Mn oxides and is

related to the crystallinity, specific surface areas, and the PZC of the oxides. In contrast to other transition elements, Cr toxicity and mobility increase with its oxidation state. Thus, the presence of Mn oxides, as oxidizing agents for Cr^{3+} in soil systems, should be considered in disposal studies (Fendorf et al., 1992).

Manganese and Fe oxides also act as final electron acceptors oxidizing organic compounds and are conversely dissolved in the process. Organic compounds that form inner-sphere complexes with the oxide surface (e.g., catechol) dissolve the Mn oxide more quickly than those compounds that form outer-sphere complexes (e.g., hydroquinone) (Stone and Morgan, 1984a, 1984b; McBride, 1987). Lovley and Phillips (1988) found evidence that microorganisms can obtain energy for growth by coupling the oxidation of organic matter to the dissimilatory reduction of Fe^{3+} and Mn^{4+}. They proposed a microbial food-chain model, in which fermentative organisms initially metabolize complex organic matter, and in the next stage, a separate group of bacteria oxidizes the fermentation products to CO_2 while reducing Fe^{3+} and Mn^{4+}. The overall process may be an important degradative pathway for organic compounds and the formation of humic material, while the reduction and dissolution of Mn oxides increases the Mn mobility and bioavailability to organisms. Hui et al. (2003), for example, showed that aromatic amines are oxidized by soil Mn oxides resulting in the release of Mn^{2+} to solution.

22.3.4 Identification

Accumulations of Mn oxides in soils are readily identified by their characteristic black–brown coloration. The effervescence observed with the addition of H_2O_2 is a usual field criterion that helps to confirm the presence of these minerals. The small amount of Mn oxides in soils, the diffuse nature of the x-ray patterns of some of the minerals, and the coincidence of diagnostic lines with those of associated matrix minerals can make their identification by XRD difficult. Thus, XRD, preferably with Fe Kα radiation, can be used only where natural segregations of the minerals occur, such as nodules, veins, or coatings. Even then, a concentration pretreatment may be necessary. Powder XRD patterns for some of the more important Mn oxide minerals are shown by Post (1992) and the most intense XRD lines of the major minerals are listed in Table 22.3. Because of the lower crystallinity, soil Mn oxides may, however, show some deviation from these patterns. A selective dissolution of Mn oxides with acidified hydroxylamine hydrochloride was proposed by Chao (1972), whereas Tokashiki et al. (1986) characterized Mn oxides by using successive sodium hydroxide, hydroxilamine hydrochloride, and DCB treatments. Concentration procedures for Mn oxides, selective chemical treatments, and identification by XRD and thermal methods are also reported by Uzochukwu and Dixon (1986). A comprehensive compilation of IR powder-absorption spectra of synthetic and naturally occurring Mn oxides is given by Potter and Rossman (1979).

Crystal structure and crystal chemistry refinements have been performed with HRTEM, electron-microprobe analysis, electron diffraction, powder XRD with Rietveld analysis

(Post and Appleman, 1988; Post and Bish, 1988; Post and Veblen, 1990), and x-ray absorption spectroscopy (Manceau et al., 1987, 1992a, 1992b; Manceau and Combes, 1988). HRTEM has led to the discovery of complex intergrowths of variable lattice periodicities in some Mn oxides (Turner and Buseck, 1979, 1981, 1983; Yamada et al., 1986).

22.4 Aluminum Oxides

Of six different Al oxide minerals, gibbsite and, less commonly, boehmite form under soil conditions. Nordstrandite and bayerite have only been identified in restricted geologic environments. Diaspore and corundum are occasionally found in bauxite deposits but are rare in soils. The relative rarity of Al oxide minerals in soils, which is in contrast to their structural Fe analogs, may be explained by the competitive formation of aluminosilicates and by the difficulty of identifying small amounts of these minerals by XRD (Taylor, 1987). More information on Al oxides is given by Hsu (1989) and Huang et al. (2002).

22.4.1 Mineral Phases

Crystallographic properties for the Al oxide minerals likely to occur in soils are listed in Table 22.4. Aluminum occurs exclusively in octahedral coordination in the Al oxides, and the

structures can be described in terms of the arrangement and linkage of Al-containing octahedra.

22.4.1.1 Hydroxides

Gibbsite (γ-Al(OH)$_3$) consists of sheets of edge-shared octahedra with two-thirds of the available octahedral sites filled with Al^{3+} ions. The occupied octahedral sites form sixfold rings, analogous to the dioctahedral sheet of phyllosilicates. The octahedral sheets are stacked along the c-axis, and the OH groups in one sheet reside directly above those in the next, rather than in the position of closest packing. The interlayer attractions are weak and are dominated by hydrogen bonding (Figure 22.1; Hsu, 1989). *Bayerite*, a second polymorphic form of Al(OH)$_3$, is analogous to gibbsite except that the OH groups of one sheet reside in the depressions between the O atoms of the next sheet and are in the close-packing position (Figure 22.1; Hsu, 1989). *Nordstrandite*, a third polymorphic form of Al(OH)$_3$, has a structure in which the stacking of the octahedral sheets alternate between the gibbsite and bayerite arrangements (Hsu, 1989). In addition to these crystalline phases, amorphous Al(OH)$_3$ may occur in soils (Süsser and Schwertmann, 1991). *Doyleite*, a fourth polymorphic form of Al(OH)$_3$, has a structure of sheets of edge-sharing octahedra (Chao et al., 1985) and is a rare hydrothermal mineral not found in soils.

[a] Numbers of the format XX-XXXX indicate ICDD file number (ICDD, 1994).

22.4.1.2 Oxyhydroxides

Diaspore (α-AlOOH) is isostructural with goethite (Figure 22.1; Ewing, 1935a, 1935b; Busing and Levy, 1958). *Boehmite* (γ-AlOOH) has the same structure as lepidocrocite (Figure 22.1). Poorly crystalline boehmite, formerly also called pseudo-boehmite, has a restricted number of unit cells along the b-axis (Tettenhorst and Hofmann, 1980).

22.4.1.3 Oxides

Corundum (α-Al$_2$O$_3$) is isostructural with hematite (Figure 22.1; Maslen et al., 1993).

22.4.2 Occurrence and Formation

Aluminum is a common element in primary silicate minerals, from which it may be released by weathering. Depending on the environmental conditions, the free Al hydrolyzes and precipitates as Al hydroxide or oxyhydroxide, and then crystallizes. The reason this fails to occur in many soils is because aluminum usually binds to silicon to form aluminosilicate clay minerals. Only in the most intense leaching environments is the Si concentration low enough that gibbsite may form. However, the detailed chemistry of Al oxide formation in soils remains obscure, mainly because of the uncertainties in the formation and the type of hydroxy polymers involved.

Synthesis studies have, so far, given an approximate outline of the probable processes of Al-hydroxide formation. The development of Al-hydroxide polymorphs appears to be related to the rate of precipitation, pH of the system, clay mineral surfaces, and the nature and concentration of inorganic and organic anions (Huang, 1988; Hsu, 1989). Only synthesis experiments related to pedogenic environments are summarized here. At room temperature, gibbsite forms in acid solutions (pH < 6) under slow hydrolysis, nordstrandite in neutral to alkaline solutions (pH > 7), and bayerite in alkaline solutions under fast hydrolysis (Hsu, 1966; Schoen and Roberson, 1970). These conditions agree with the natural occurrence of gibbsite in highly weathered acidic soils, whereas nordstrandite and bayerite have been found in association with limestone materials. Thermodynamically, gibbsite is the most stable of the three Al(OH)$_3$ polymorphs (Hemingway et al., 1991).

Anions that have strong affinity for Al^{3+}, such as SO$_4^{2-}$, CO$_3^{2-}$, PO$_4^{4-}$, and SiO$_3^{2-}$, may interfere with the crystallization of Al(OH)$_3$ (Huang, 1988; Hsu, 1989). Organic ligands like citric, malic, tannic, aspartic, and fulvic acids block the coordination sites of polynuclear Al ions and restrain the hydrolysis, inhibiting the crystallization of Al(OH)$_3$ and influencing the nature of the precipitated compound (Kodama and Schnitzer, 1980; Violante and Violante, 1980; Violante and Huang, 1985; Singer and Huang, 1990). This explains why little or no gibbsite is found in the A horizon of acidic soils high in organic matter and exchangeable Al, while it is found in greater quantities in deeper horizons.

The pathway for gibbsite formation by direct desilication of primary Al silicates or through clay mineral intermediates (Jackson, 1964) is conditioned by the intensity of leaching, which,

in turn, is affected by rainfall, temperature, parent rock, topography, groundwater table, vegetation, and time. Environments with warm temperatures, high rainfall, and free drainage favor desilication and leaching of ions, as well as mineralization of organic matter. Oxisols and laterites found in these environments may have significant amounts of gibbsite associated with kaolinite and Fe oxides (Curi and Franzmeier, 1984; Macedo and Bryant, 1987). Gibbsite is frequently a minor component in ultisols, which are widespread in humid tropical, subtropical, and temperate regions (Allen and Hajek, 1989). High amounts of gibbsite may be found under temperate climates in deeper parts of soil profiles submitted to higher leaching rates (Norfleet et al., 1993; Ogg and Baker, 1999). The porosity of the soil parent material is important in determining whether or not gibbsite forms. In Kenya, for example, soils formed in porous volcanic ash on the slopes of Mt. Kenya contain considerably more gibbsite than soils from western Kenya formed from hard igneous and metamorphic rocks (Obura, 2008).

Nordstrandite has been found in nature as crystals radiating into solution cavities in limestone from Guam (Hathaway and Schlanger, 1965) and as small pellets in a limestone soil from Borneo (Wall et al., 1962). Bayerite found in calcareous material in Israel probably formed under hydrothermal conditions (Gross and Heller, 1963). The apparent rarity of bayerite and nordstrandite in soils may reflect identification difficulties, due to their low concentration and/or masking by the presence of gibbsite.

The same factors may be responsible for the rare reports of boehmite in soils (Taylor, 1987). Boehmite has been identified in lateritic materials (Gilkes et al., 1973) and together with diaspore in bauxites (Vgenopoulos, 1984). Boehmite often occurs in bauxite deposits in association with gibbsite, from which it is considered to form through partial dehydration by diagenesis or hydrothermal alteration. Hughes et al. (1994) identified boehmite in native American artifacts from an Ordovician-age paleosol in northwestern Illinois. The formation of poorly crystalline boehmite has been attributed to the presence of foreign ions during crystallization (Hsu, 1967). Since poorly crystalline boehmite alters to crystalline Al(OH)$_3$ polymorphs on removal of the foreign ions from the environment, the occurrence of crystalline boehmite in soils, other than those derived from bauxite, may be less common than believed (Taylor, 1987).

Diaspore in association with minor amounts of goethite has been identified as a surface weathering product formed by the desilication of a kaolinitic clay in Missouri (Keller, 1978). The possible influence of Fe in diaspore formation is supported by synthesis experiments and natural rock weathering and bauxite occurrences (Taylor, 1987). The formation of Fe-substituted diaspore is, however, unlikely because the large Fe^{3+} does not fit into the diaspore structure, in contrast to the substitution of the smaller Al^{3+} in the larger goethite structure (Davies and Navrotsky, 1983). In confirmation, Fe in a diaspore crystal has been identified as a hematite-like cluster (Hazemann et al., 1992).

Corundum occurs in pegmatites and other rocks associated with nepheline syenites, in high-grade aluminous metamorphic rocks, in aluminous xenoliths in igneous rocks, in

metamorphosed bauxitic deposits, and as a detrital mineral in sediments (Deer et al., 1992). Reports of corundum in soils are scarce, but because of its high resistance to weathering, it can be found as a residual mineral of igneous or thermally metamorphosed rocks, like in lateritic bauxites of Australia (Taylor et al., 1983) and in Brazilian Oxisols (Macedo and Bryant, 1987). In some Australian soils derived from corundum-free rocks, the presence of corundum is attributed to the heating of the soil by bush fires (Wells et al., 1989). The corundum may have formed in association with hematite by the dehydroxylation of Al-goethite. The associated crystallization of isostructural hematite may have acted as a template for the nucleation of corundum, thereby reducing the activation energy and enabling its formation at relatively low temperature via the epitaxial growth on hematite.

22.4.3 Influence on Soil Properties

Because of the high surface area (100–220 m^2 g^{-1}), high PZC (pH 5–9), and a variable surface charge, Al oxides favorably chemisorb heavy metals (Cu, Pb, Zn, Ni, Co, Cd) and anions (PO$_4^{4-}$, SiO$_3^{2-}$, MoO$_4^{2-}$, SO$_4^{2-}$, catechols) (Hingston et al., 1974; McBride and Wesselink, 1988; McBride, 1989). The adsorption is related to the reactive (singly coordinated OH$^-$ groups at crystallite edges) rather than the total surface area. The high P retention in Oxisols and Ultisols is usually related to the content of gibbsite, in addition to that of Fe oxides (Juo, 1981; van Wambeke, 1992). Synthesis studies have shown the effectiveness of Al(OH)$_3$ precipitates in improving the physical properties of soils and clay minerals (see Hsu, 1989). Aluminum oxides, mainly gibbsite, in addition to Fe oxides, are strongly associated with the aggregation of Oxisols and Ultisols, but the mechanism of aggregation is unclear.

22.4.4 Identification

Crystalline Al oxides can be identified and quantified by XRD, thermal analysis, IR, and EM with a combination of several methods being necessary. Currently, no selective dissolution methods are known for the specific dissolution of crystalline and noncrystalline Al forms in soil samples, but acid NH$_4^+$ oxalate treatment (Schwertmann, 1964) is frequently used to estimate the content of undefined, poorly crystalline Al forms in soils. The problems inherent in the identification of poorly crystalline Al oxides in the presence of clay minerals are illustrated by Violante and Huang (1994). By XRD analysis, the detection limit of poorly crystalline boehmite in samples containing kaolinite or montmorillonite was approximately 30%–40%. When both kaolinite and montmorillonite were present, however, the identification by DTA, IR, or TEM often failed even for concentrations of boehmite as high as 50%–80%.

Under the electron microscope, well-crystallized gibbsite occurs as hexagonal plates (Hsu, 1989) or as elongated hexagonal rods in synthetic crystals (Tait et al., 1983). Euhedral gibbsite crystals from a bauxite zone in a deep lateritic weathering profile are shown in Figure 22.5. Bayerite frequently occurs as a triangular pyramid, with its long direction perpendicular to the basal
FIGURE 22.5   Scanning electron micrograph from a bauxitic zone in a deep lateritic profile from the Jos plateau, Nigeria, showing hematite crystal aggregates on large euhedral gibbsite crystals. (From Zeese, R., U. Schwertmann, G.F. Tietz, and U. Jux. 1994. Mineralogy and stratigraphy of three deep lateritic profiles of the Jos plateau (central Nigeria). Catena 21:195–214.)

plane (Schoen and Roberson, 1970; Violante and Jackson, 1981; Hsu, 1989). Synthetic nordstrandite shows rectangular plates, elongated parallelograms, ill-defined ovoidal particles, or clusters of acicular crystals (Shoen and Roberson, 1970; Violante and Jackson, 1979, 1981; Violante et al., 1982; Tait et al., 1983). With the exception of gibbsite, many of these crystal shapes seem to occur only in synthetic Al oxides.

22.4.4.1 X-Ray Diffraction

The main XRD peaks of the Al oxides are listed in Table 22.4. For specimens with poor crystallinity, these diffraction peaks may not be completely resolved. Gibbsite in soils can be quantified by XRD, but it will not be detected if its content is below about 50 g kg^{-1} (Jackson, 1969). The strongest peak for boehmite is the d(020) at 6.11 Å, while very fine boehmite particles show a broadening and an apparent line shift of the d(020) peak to larger d-spacings due to a diffraction effect (Tettenhorst and Hoffman, 1980).

22.4.4.2 Thermal Analysis

DTA is frequently used for the identification of Al hydroxides and oxyhydroxides (Mackenzie, 1970, 1972; Karathanasis and Harris, 1994). The presence of 10 g kg^{-1} gibbsite can be detected by DTA, and its amount can be estimated by comparing the 300°C–330°C endothermic peak with those of standards. The peak temperature for bayerite is only slightly lower than that for gibbsite, so that their differentiation in natural samples is impossible (Karathanasis and Harris, 1994). In soil samples, the 300°C–330°C peak may overlap with that of goethite, requiring an additional DTA curve after the removal of goethite with sodium dithionite (Jackson, 1969). Diaspore yields an endothermic peak at 540°C, whereas boehmite has a peak that occurs in the range of 450°C–580°C depending on crystallinity and particle size. The overlap with the kaolinite peak at 550°C limits the identification of these oxyhydroxides.

22.4.4.3 Infrared Absorption Analysis

Characteristic OH-stretching absorption spectra have been used to identify $Al(OH)_3$ and AlOOH polymorphs in monomineralic samples. Gibbsite shows three absorption bands and another doublet, with reported bands for well-crystallized natural gibbsites at 3622, 3627, 3460, 3396, and 3384 cm^{-1}. Each of the absorption bands may shift slightly to lower wave numbers with decreasing crystallinity (Elderfield and Hem, 1973). The 3622 cm^{-1} absorption band is coincident with that of kaolinite and micaceous clays (Farmer and Russel, 1967), thus precluding its use for the identification of gibbsite. Boehmite and diaspore each show two OH-stretching bands, boehmite at 3087 and 3283 cm^{-1} and diaspore at 2922 and 2990 cm^{-1} (Ryskin, 1974). Raman microprobe spectroscopy offers an alternative procedure in characterizing $Al(OH)_3$ polymorphs in soils (Rodgers, 1993).

22.5 Silicon Oxides

The Si oxides occurring in soils are given in Table 22.5. In nature, the SiO_2 polymorphs (quartz, tridymite, and cristobalite) occur as both higher temperature or β-phases and lower temperature or α-phases. In soils, however, only the α-phases are usually found. Opal is a hydrated form of Si of both biogenic and inorganic origin. Microcrystalline quartz, or microquartz, occurs in the form of chalcedony and chert (Heaney, 1994). Microcrystalline fibrous α-quartz, in the form of chalcedony, usually occurs as a secondary infilling of seams and cavities within rocks, sometimes creating concentrically banded agates or geodes. An intergrowth of authigenic microcrystalline α-quartz grains, which range in size from <1 to 50 μm, occurs in highly silicified sedimentary rocks in the form of chert (Knauth, 1994). More information about Si oxides can be found in Drees et al. (1989), Heaney et al. (1994), and Monger and Kelly (2002).

22.5.1 Mineral Phases

The Si oxides are tectosilicates. The repeating unit is a SiO_4 tetrahedron in which each O is linked to Si atoms of adjacent tetrahedra, forming a 3D framework structure. This contrasts with the Fe, Al, Mn, and Ti oxides in which the basic unit is a cation in octahedral coordination. The pattern of the tetrahedral linkage is different for each Si oxide polymorph, and this difference is reflected in their structural, physical, and chemical properties. The structures of the α-phases are closely related to those of their high-temperature β-phase equivalents. *Quartz* consists of paired helical chains of corner sharing SiO_4 tetrahedra that spiral along the Z-axis (Heaney, 1994). The intertwined chains produce open channels parallel to c (Z) that appear hexagonal in projection (Figure 22.1). In *tridymite* and *cristobalite*, the idealized fundamental module consists of a sheet containing six-member rings of SiO_4 tetrahedra, with the tetrahedra alternately pointing above and below the plane defined by the basal oxygen atoms (Heaney and Banfield, 1993). Tridymite and cristobalite are differentiated by a different stacking arrangement of this tetrahedral sheet. In tridymite, the sheets are stacked such that the hexagonal rings (ditrigonal and oval rings in α-tridymite structures) lie directly over one another, creating continuous tunnels normal to the sheets (Figure 22.1). These tunnels account for the lower density of tridymite (2.26 g cm^{-3}) as compared to quartz (2.65 g cm^{-3}). In cristobalite, the stacking involves three sheets that are translated relative to one another such that the hexagonal rings

TABLE 22.5 Silicon Oxide Minerals: Crystallographic Properties and d Values for the Six Most Intense Diffraction Lines

[b] Numbers of the format XX-XXXX indicate ICDD file number (ICDD, 1994).

(oval rings in α-cristobalite) do not superimpose (Figure 22.1). Thus, cristobalite lacks the continuous tunnels normal to the layers as in tridymite, but tunnel structures are formed parallel to the layers. Thus, the density of cristobalite is only slightly higher than that of tridymite ($2.32\,g\,cm^{-3}$).

Opal is classified into three structural groups based on XRD powder patterns: Opal-C (well-ordered α-cristobalite), opal-CT (disordered α-cristobalite, α-tridymite), and opal-A (highly disordered, nearly amorphous) (Jones and Segnit, 1971; Deer et al., 1992), in a sequence of decreasing structural order. In opal-C, the stacking is predominantly cristobalitic, which is revealed by weak superstructure XRD reflections characteristic of α-cristobalite. Opal-CT consists of random stackings of α-cristobalite- and α-tridymite-like arrangements, yielding a disordered crystal structure. The microstructure of opal-CT is composed of small spheres less than $5\,\mu m$ in diameter, called lepispheres, which consist of an interpenetrative growth of tiny cristobalite and tridymite blades (Hesse, 1988; Graetsch, 1994). Opal-A is a noncrystalline hydrous Si polymorph ($SiO_2 \cdot nH_2O$) differing from the crystalline polymorphs in that it lacks long-range atomic order. The microstructure of opal-A shows the closest packing of spheres of Si with diameters ranging from 10 to $50\,nm$ (Greer, 1969) with water filling the interstices (Graetsch, 1994). The specific gravity of biogenic opal from soils and plants varies continuously over the range 1.5–2.3, with modal values from 2.10 to $2.15\,g\,cm^{-3}$ (Drees et al., 1989). The broad range is a function of the submicron opal structure, H_2O content, occluded organic matter, and microscopic voids.

Quartz is one of the purest minerals known, and due to its more closed structure, it is purer than the other Si oxide polymorphs (Drees et al., 1989). Nevertheless, common trace elements in quartz, either interstitial or as substitutions, occur and include Al, Ti, Fe, Na, Li, K, Mg, Ca, OH. Both cristobalite and tridymite, which are also the major structural constituents of opal-CT, may accommodate more impurities than quartz because of their more open framework structure. The predominant impurity is Al, with lesser amounts of Fe, Ti, K, Na, Ca, and Mg. Opal-A contains 850–950 g kg^{-1} of SiO_2, 40–90 g kg^{-1} of bound H_2O, and significant amounts of occluded, chemisorbed, or solid-solution impurities of Al, Fe, Ti, Mn, P, Cu, N, C, alkalies, and alkaline earths (Drees et al., 1989).

22.5.2 Occurrence and Formation

Quartz is a common constituent in many igneous, sedimentary, and metamorphic rocks, and also occurs as a secondary mineral, forming cementing materials in sediments. Tridymite is a typical mineral of acid volcanic rocks together with cristobalite that also occurs in basaltic rocks. Tridymite is also a common constituent of highly metamorphosed impure limestones and arkoses adjacent to basic igneous intrusions, while cristobalite occurs in metamorphosed sandstones and sandstone xenoliths in basic rocks. Opal is found in sedimentary, volcanic, and marine environments (Deer et al., 1992). Thus, quartz is the most abundant Si oxide in soil environments, cristobalite occurs

in soils developed from volcanic materials, opal may be a significant component of soils, but tridymite occurs only rarely.

Quartz in soils is mainly a primary mineral, inherited from the parent material. The higher stability of quartz compared to other silicate minerals is explained by its crystallization from magma closer to present earth-surface conditions. The higher stability of quartz relative to the other Si oxide polymorphs is due to a denser packing of the crystal structure and a higher energy required to break the Si–O–Si bond. Quartz in chert forms through a diagenetic transformation from opal-A via opal-CT and opal-C (Hesse, 1988). As demonstrated experimentally, quartz may also precipitate directly (Mackenzie and Gees, 1971). Authigenic quartz in the form of chemical precipitations and grain overgrowths frequently occurs in sediments (carbonates, sandstones) and is believed to form in soils, too (Drees et al., 1989).

Quartz is generally concentrated in the sand and silt fractions of soils, with a lower frequency in the coarse-clay fraction ($0.2–2\,\mu m$). The depth distribution of quartz is a function of parent material and degree of weathering (Drees et al., 1989). In relatively undifferentiated soils (Entisols and Inceptisols), distributions of quartz reflect mainly variations in parent material. Quartz may comprise >90% of the inorganic fraction of Quartzipsamments. In Aridisols, quartz is generally abundant due to restricted weathering, while in moderately weathered soils (Spodosols, Alfisols, Mollisols, and Ultisols), the eluvial horizons are enriched in quartz relative to the parent material due to the weathering and removal of less resistant minerals. Conversely, illuvial horizons have lower quartz contents than eluvial horizons or parent materials due to the dilution by silicate clays, carbonates, or oxides. Highly weathered and leached Oxisols have only very low amounts of quartz left in the clay fraction.

Opal-CT, opal-C, and α-cristobalite are usually limited to specific geographic regions and rock-stratigraphic units. Opal-C and α-cristobalite have been reported in Andepts and other soils derived from volcanic material in South America, New Zealand, Central America, and Japan. Opal-CT has been identified in bentonites, siliceous shales, and indurated silicates. As a consequence, soils developed in these materials commonly contain opal-CT. It is also a primary constituent of many cherts, porcelanites, fossil wood, silcretes, and some duripans (Drees et al., 1989). According to synthesis experiments and evidence from diagenetic environments, opal-A transforms to opal-CT and quartz by a series of dissolution–precipitation reactions (Kastner et al., 1977; Williams and Crerar, 1985; Williams et al., 1985, Cady et al., 1996). The conversion is dependent on temperature, pressure, pH, pore solution chemistry, and specific surface area. As the transformation is mediated by clays, oxides, and carbonates, it is assumed to occur in soils (Drees et al., 1989).

Opal-A may form by both organic and inorganic processes in pedogenic environments. Biogenic opal-A originates from Si accumulated by plants and aquatic organisms, and thus occurs under a wide range of environmental conditions (Jones and Beavers, 1964; Wilding and Drees, 1971).
FIGURE 22.6 Scanning electron micrograph of an opal phytolith isolated from a forest soil. (From Drees, L.R., L.P. Wilding, N.E. Smeck, and A.L. Senkayi. 1989. Silica in soils: Quartz and disordered silica polymorphs, p. 913–974. *In* J.B. Dixon and S.B. Weed (eds.) Minerals in soil environments. 2nd edn. SSSA, Madison, WI.)

Biogenic opal is a minor but nearly ubiquitous constituent of soils, with opal phytoliths (Figure 22.6) representing the major form in nonaquatic environments, while sponge spicules, diatoms, and radiolaria are the main opal form in aquatic environments and limestone residuum (Jones and Beavers, 1964; Wilding and Drees, 1971). Amounts of opal phytoliths in soils commonly range from <1 to 30 g kg^{-1}, usually occurring in the 5–20 and 20–50 μm size fractions and decreasing with soil depth (Drees et al., 1989). Phytoliths are recognized as the principal sink and source of Si in soil solutions (Lucas, 2001; Farmer et al., 2005).

Opal-A, which forms when the conditions favor supersaturation of Si in soil solution (Jones and Handreck, 1967), occurs as nodules and as a primary cement for indurated soil horizons (duripans) and silcretes. Such soils usually have pH and moisture regimes favoring solubilization and translocation of Si to lower positions in the soil profile. Geographically, duripans are restricted to materials that provide soluble Si, such as pyroclastics and intermediate and basic igneous rocks (Flach et al., 1969; Soil Survey Staff, 1975). According to Flach et al. (1969), pedogenic transformation of opal to quartz is believed to occur in duripans and in Si-cemented soils. Silica released by weathering of silicate minerals may precipitate as amorphous SiO$_2$ on soil particles, forming bridges between mineral grains, leading to the hardness and brittleness of fragipans (Franzmeier et al., 1989; Karathanasis, 1989).

At ambient temperature and neutral pH, the solubility of amorphous Si in soils is approximately 50–60 mg Si L^{-1} and that of quartz is commonly 3–7 mg Si L^{-1}. The solubility of Si oxides is a function of temperature, pH, particle size, chemical composition, and the presence of a disrupted surface layer. For both crystalline and amorphous Si polymorphs, it is essentially constant between the pH limits of 2 and 8.5, increasing rapidly above pH 9 due to the ionization of monosilicic acid.

The presence of organic molecules greatly enhances the dissolution rates of Si oxides. The dissolution of biogenic opal and quartz increases as particle size decreases due to the increase in surface area (Drees et al., 1989). Chemisorption of metallic ions such as Al, Fe, Mg, Ca, Cu, Pb, and Hg to Si surfaces reduces the dissolution rates of Si due to the formation of relatively insoluble Si coatings (Drees et al., 1989), thus increasing the stability of Si oxides. Oxides of Fe and Al, by acting as a soluble Si sink, greatly increase the dissolution rates of amorphous Si oxides and reactive uncoated quartz surfaces. Dissolution (weathering) of Si oxides is induced by the reduction of Si levels in soil solution by leaching and plant uptake. Dissolution of quartz initiates below approximately 3 mg of Si L^{-1} (Kittrick, 1969).

22.5.3 Influence on Soil Properties

Noncemented soils comprised dominantly of quartz are nonplastic due to the weak cohesion (van der Waals forces) that develops between Si particles and show low water-retention capacity and high hydraulic conductivity. Duripans, cemented by even small amounts of Si, are hard to extremely hard when dry, have high unconfined compressive strength, and resist dispersion in Na hexametaphosphate (Flach et al., 1974).

Due to their essentially uncharged, poorly hydrated surface, crystalline Si oxides have relatively small effects on the physicochemical activity affecting the soil–plant relationship and act as a diluent to the much more reactive clay minerals and oxides of Fe, Al, and Mn. Silica is not essential for the growth of most plants, but orthosilicic acid, H$_4$SiO$_4$, has a beneficial effect on the growth of some plants (Jones and Handreck, 1967). Rice and sugarcane, for example, often respond to fertilization with very soluble Si sources such as Si slag.

Due to its ubiquity, abundance, resistance to weathering, and immobility, quartz has been often used as an index mineral for weathering and soil formation (Barshad, 1964; Sudom and St. Arnaud, 1971). Extensive leaching may, however, drastically increase the solubility of primary quartz (Little et al., 1978; Asumadu et al., 1988; Pye and Mazzullo, 1994), and authigenic (Breese, 1960) as well as biogenic quartz may form in soils (Wilding and Drees, 1974), thus restricting the use of quartz as an index mineral.

The isotopic composition of quartz (^{18}O), which depends on the temperature of formation, has been used to identify eolian additions to soils (Clayton et al., 1972; Mizota and Matsuhisa, 1995) and the formation of authigenic opaline Si in volcanic ash soils (Mizota et al., 1991).

Opal phytoliths have been used to trace the origin of colluvial sediments (Lutwick and Johnston, 1969) and to identify surface horizons of paleosols (Dormaar and Lutwick, 1969). Depth distributions of sponge spicules may be useful to identify lithological discontinuities, and opal of aquatic organisms (diatoms,

sponge spicules, and siliceous shells) provides direct evidence that the parent material of the soil is of marine or lacustrine origin (Jones and Beavers, 1963, 1964; Wilding and Drees, 1968, 1971). Biogenic opal has been extensively used to reconstruct the vegetative history of soils (Drees et al., 1989; Fisher et al., 1995; Staller, 2002). The $^{13}C/^{12}C$ isotope ratio of C occluded in opal phytoliths was used to establish the succession of C3 and C4 grasses, providing a quantitative method for monitoring climatic changes (Kelly et al., 1991).

22.5.4 Identification

Silica oxides can be identified by XRD, SEM, microprobe analysis, IR, and light microscopy. Opal-CT and opal-A may need to be concentrated by particle-size fractionation, specific gravity, and/or differential dissolution. Counting particle size separates under the light microscope is the simplest method of quantifying Si oxides but is limited in resolution (5–10 μm) (Drees et al., 1989). A review of methodologies for extraction of amorphous Si from soils and aquatic sediments is given by Sauer et al. (2006) and Sacconne et al. (2007).

22.5.4.1 Crystal Form, Habit, and Color

In soils, quartz generally occurs as anhedral grains, rarely exhibiting the characteristic prismatic habit of macrocrystals. Angular grains are generally the result of mechanical fracturing, while rounding is a result of physical attrition during both transport and solution. Overgrowths on quartz grains may suggest long-term stable environments. Particles <100 μm are commonly shaped like flat plates due to cleavage (Drees et al., 1989). Thus, quartz grain surface morphology may be used to elucidate mineral origin and past and/or present chemical and physical environment.

Opal-CT is commonly observed in sediments as small (<10 μm) lepispheres. The morphology of opal-A of biogenic origin is closely related to the biological cell or structure in which it originates: opal of forest origin consisting of cellular incrustations with numerous thin-sheet structures (Figure 22.6); opal of grass consisting of solid polyhedral structures resulting from the silicification of the entire cell; and opaline microfossils of sponge spicules, diatoms, and shells (Drees et al., 1989).

Pure Si oxides are colorless but chemical impurities may impart various colors. Quartz is usually colorless and transparent, or white, with a vitreous luster. Cristobalite is white to milky white and ranges from translucent to opaque. The color and degree of translucency of opal-CT seem to depend on the aggregation of lepispheres. For opal-A, color is not a diagnostic criterion because it is strongly affected by occluded chemical impurities and light interference and scattering. In transmitted light, biogenic opal isolated from soils ranges from colorless or light tan to various shades of brown or black (Drees et al., 1989).

22.5.4.2 X-Ray Diffraction

The diagnostic parameters for Si oxides are presented in Figure 22.7 and Table 22.5. Quartz is easily identified by its most intense reflections at 4.26 and 3.34 Å, even in mixed mineral
FIGURE 22.7 XRD patterns for quartz, synthetic cristobalite, opal-CT, and opal-A (Cu Kα radiation, peak position in nanometers). (Modified from Drees, L.R., L.P. Wilding, N.E. Smeck, and A.L. Senkayi. 1989. Silica in soils: Quartz and disordered silica polymorphs, p. 913–974. *In* J.B. Dixon and S.B. Weed (eds.) Minerals in soil environments. 2nd edn. SSSA, Madison, WI.)

assemblages. The accuracy of the quantitative determination of quartz depends on sample preparation and the diffraction peak used (Rowse and Jepson, 1972). For well-ordered or α-cristobalite, the 4.04 Å peak is the main clue in mixed samples provided that no feldspars are present. Opal-C gives a pattern resembling that of α-cristobalite, except for slight line broadening and minor evidence of tridymite stacking. Opal-CT usually exhibits broad cristobalite peaks at about 4.1 and 2.5 Å and a peak at 4.3 Å, which is attributed to tridymite. The wide variations in the intensity and line profiles make its quantification by XRD difficult. The short-range order in opal-A produces a diffuse, broad x-ray hump centered at about 4.0 Å.

22.5.4.3 Thermal Properties

Quartz exhibits a sharp endothermic DTA peak at about 570°C (Drees et al., 1989), which may not be evident for microcrystalline quartz (<0.05 μm). Well-ordered synthetic cristobalite has a characteristic endothermic peak at about 260°C, whereas opal-CT and opal-A do not yield a characteristic endotherm below 600°C.

According to Rowse and Jepson (1972), DTA is better than either XRD or chemical techniques for detecting small quantities of quartz in clay materials.

22.5.4.4 Infrared Spectroscopy

All tectosilicates are characterized by Si–O–Si stretching vibrations between 950 and 1200 cm^{-1} and by O–Si–O bending vibrations between 400 and 550 cm^{-1}. Quartz is distinguished from the other Si polymorphs by a distinctive absorption band at 692 cm^{-1} and two strong doublets, one at 395 and 370 cm^{-1} and the other at 800 and 780 cm^{-1} (Drees et al., 1989). The latter doublet has been used also for the quantification of quartz (Chester and Green, 1968). This method is, however, restricted to samples <1 μm in particle size and free of other Si polymorphs.

The disordered Si polymorphs, opal-C, opal-CT, and opal-A, have a single band around 800 cm^{-1} in common. Well-ordered cristobalite and opal-C show additional bands at 620 and 380 cm^{-1}. Opal-A of biogenic origin is characterized by much weaker and broader absorption bands at 460 and 1100 cm^{-1} as compared to the better crystallized polymorphs and an additional weak band at 965 cm^{-1} (Drees et al., 1989).

22.6 Titanium and Zirconium Minerals

Of all Ti and Zr compounds in soil and weathered materials, the Ti oxides (rutile, anatase, and ilmenite) and the Zr silicate (zircon) are the most ubiquitous. The principal Ti and Zr minerals are listed in Table 22.6. Additional information about Ti and Zr minerals can be found in Milnes and Fitzpatrick (1989), Lindsley (1976, 1991), and Fitzpatrick and Chittleborough (2002). Titanomagnetite and titanomaghemite are described in Section 22.2.

22.6.1 Mineral Phases

Titanium occurs primarily in octahedral coordination, and like the Fe and Mn oxides, the structures of the various Ti oxide minerals can be described in terms of the different arrangement of the Ti-containing octahedra (Lindsley, 1976; Waychunas, 1991; Heaney and Banfield, 1993).

Rutile (TiO$_2$) is isostructural with pyrolusite and manganite, consisting of single chains of edge-sharing TiO$_6$ octahedra (Figure 22.1; Heaney and Banfield, 1993). *Anatase* consists of TiO$_6$ octahedra that share four O–O edges, two at the top and two at right angles at the bottom. The octahedra outline a 3D framework, rather than distinct chains (Figure 22.1; Waychunas, 1991). Schwertmann et al. (1995b) reported the substitution of Ti^{4+} by Fe^{3+} up to 0.1 mol fraction in pedogenic and synthetic anatase. Charge compensation is achieved by the incorporation of structural OH. *Brookite* has a more complex structure than rutile or anatase, consisting of deformed TiO$_6$ octahedra sharing three O–O edges to form staggered, cross-linked chains that are oriented along the c-axis (Figure 22.1; Lindsley, 1976). *Ilmenite* (FeTiO$_3$) is almost isostructural with hematite, with one-half of the Fe atoms replaced by Ti, so that the Fe^{3+}–O$_3$–Fe^{3+} units in hematite become Fe^{2+}–O$_3$–Ti^{4+} units in ilmenite (Figure 22.1; Lindsley, 1976). *Pseudobrookite* (ideally Fe$_2$TiO$_5$) has strongly distorted octahedra but can be described in terms of an ideal cubic close packing anion arrangement (Figure 22.1; Waychunas, 1991). The two types of octahedral sites are M1 and M2 in the ratio 1:2, ideally occupied by Fe^{3+} and Ti^{4+}, respectively. *Pseudorutile* (Fe$_2$O$_3$·nTiO$_2$·mH$_2$O; $3 < n < 5$ and $1 < m < 2$) is a structurally disordered and poorly characterized mineral formed by the alteration of ilmenite. Its structure is based on a hexagonal closest packing of O^{2-} anions and has been described as an intergrowth of a rutile-type structure with a goethite-type

TABLE 22.6 Titanium and Zr Oxide Minerals: Crystallographic Properties and d Values for the Six Most Intense Diffraction Lines

Mineral	Chemical Formula	Crystal System, Space Group	Unit-Cell Dimensions (Å)	Six Most Intense Diffraction Lines d Value (Å), Relative Intensity						References[a]

structure (Figure 22.1; Grey et al., 1983). *Zircon* ($ZrSiO_4$) is an orthosilicate with a structure consisting of chains of alternating edge-sharing SiO_4 tetrahedra and $[ZrO_8]$ triangular dodecahedra. The chains are joined laterally by dodecahedra-sharing edges in an arrangement that produces unoccupied octahedral voids (Speer, 1982).

22.6.2 Occurrence and Formation

Rutile, anatase, ilmenite, and less frequently brookite are found as accessory minerals in many igneous and metamorphic rocks and as detrital minerals in sediments, although anatase is often also of authigenic origin (Deer et al., 1992). The Ti and Zr minerals in soils may be residual minerals inherited from the parent material, formed through weathering of Ti- and Zr-bearing minerals, or authigenic (Milnes and Fitzpatrick, 1989). Rutile, anatase, ilmenite, and zircon are commonly residual minerals occurring in the sand and silt fractions of a variety of soils. Ilmenite may weather to pseudorutile and mixtures of rutile, anatase, and Fe oxides. Some evidence indicates that anatase and ilmenite weathering occurs by organic acids in A horizons of Scottish podzols (Berrow et al., 1978), and weathering features were observed on the surface of zircon and rutile grains of Australian Spodic Quartzipsamments (Tejan-Kella et al., 1991).

Many examples of secondary Ti oxides formed through weathering of primary minerals are found in saprolites and in soils. The data on the secondary or authigenic formation of Zr minerals are, however, controversial (Milnes and Fitzpatrick, 1989). The alteration of ilmenite under oxidizing conditions leads to the formation of pseudorutile (Grey and Reid, 1975; Anand and Gilkes, 1984b) but, at this stage, there is no clear evidence that it also takes place under pedogenic conditions (Berrow et al., 1978). Authigenic formation of poorly crystalline anatase as an alteration product of sphene was observed in peaty podzols from Scotland (Berrow et al., 1978). In conclusion, basic aspects of the Ti and Zr minerals, such as whether the minerals are relict or pedogenic, and the conditions responsible for their weathering and formation in soils, are still unresolved (Taylor, 1987; Milnes and Fitzpatrick, 1989).

22.6.3 Influence on Soil Properties

Because of their generally low concentrations in soils, there is little evidence of the effect of Ti and Zr minerals on soil reactivity. Only in tropical soils where their concentrations are much higher some effects may be expected. The broken-edge bonds of anatase are hydroxylated and can exhibit variable charge characteristics (Fitzpatrick et al., 1978). The rutile and anatase surface has hydroxyl groups with different reactivities (Tanaka and White, 1982) that can adsorb and retain phosphate and arsenate (Cabrera et al., 1977; Fordham and Norrish, 1983).

Because ilmenite and zircon are generally very resistant in soils, they may be used as reference minerals in weathering and soil genesis studies (Bleeker, 1972; Mitchell, 1975; Claridge and Weatherhead, 1978; Tejan-Kella et al., 1991). The immobility of these minerals must, however, be previously assured (Colin et al., 1993; Anda et al., 2009).

22.6.4 Identification

As Ti and Zr minerals can occur in different particle-size fractions and exhibit variable crystallinity, a variety of techniques may be necessary to identify and characterize them. Optical microscopy is a useful technique for examining and identifying these minerals, both in undisturbed form in thin sections and as components separated by physical or chemical techniques (Mitchell, 1975). A combination of XRD, IR absorption, DTA, and electron microprobe techniques is useful for identifying the Ti and Zr minerals in the sand and silt fractions of soils but may be less satisfactory for the clay fractions due to the interference of layer silicates (Milnes and Fitzpatrick, 1989). TEM along with energy-dispersive x-ray analysis of individual particles can be used to identify Ti oxide crystals in soil clay fractions (Figure 22.8). Titanium oxides may be concentrated in kaolinitic soils by dissolution of clay minerals in boiling 5 M NaOH alone (Norrish and Taylor, 1961) or by a combination of boiling 5 M KOH and DCB treatments (Zeese et al., 1994). Amorphous Ti oxides can be separated from more crystalline forms by extraction in acid ammonium oxalate (Fitzpatrick et al., 1978). Minor amounts of anatase (>0.02%) can be identified by Raman spectroscopy (Murad, 1997). Tejan-Kella et al. (1991) described an SEM method to characterize microtextural features of zircon and rutile grains. In XRD of the clay fraction, the strong, sharp anatase peak at 3.52 Å (Table 22.6) is often clearly resolved after the interfering 3.59 Å kaolinite line has been eliminated by heating at 550°C.

Poorly Crystalline Aluminosilicate Clay Minerals

James Harsh
Washington State University

This chapter covers the poorly crystalline aluminosilicate materials, commonly known as allophane and imogolite. With dimensions generally less than 50 nm, allophane and imogolite are naturally occurring nanoparticles. Their solubility, high specific surface area, variable charge, and unique physical behavior impart special properties to soils that contain them. Although often associated with soils formed from volcanic material (Andisols), allophane and imogolite are found within a wide range of soil orders and derived from a variety of parent materials. Ferrihydrite, a poorly crystalline iron oxide that often occurs with allophane and imogolite, is covered elsewhere in this handbook. A timely review by Parfitt (2009) considered the role of allophane and imogolite in biogeochemical processes, Dahlgren et al. (2004) reviewed volcanic soils, and Floody et al. (2009) discussed industrial applications of allophane and other natural nanoclays.

23.1 Structure of Poorly Crystalline Materials

23.1.1 Definition of Short-Range Ordered Materials

Crystalline materials exhibit long-range order in their atomic structure. Structural features repeat over scales of at least micrometers in a single crystal or over several particles in a powder. Such minerals display narrow x-ray diffraction peaks and their crystal habit can be directly observed at the scale of an optical microscope or by the naked eye in the case of large crystals. Amorphous materials, on the other hand, exhibit no order, even in the local

environment of the atoms. The atoms are arranged in a variety of states and structures where bond lengths, coordination, and geometry vary from site to site. Poorly crystalline materials fall in between these two extremes, showing short-range, medium-range, or limited long-range order. Short-range order is observable by techniques that probe the local environment of each atom, such as nuclear magnetic resonance (NMR) or x-ray photoelectron spectroscopy. X-ray diffraction peaks are indicative of, at least, medium-range order, whereas long-range order is detectable by electron microscopy. Poorly crystalline materials lack medium-range repetition of structural units in at least one of the three spatial dimensions; that is, well defined electron or x-ray diffraction patterns (XRD) are not produced. Allophane and imogolite practically represent the range from amorphous to crystalline materials (Fyfe et al., 1987). In the interest of brevity, allophane, imogolite, and poorly crystalline iron hydrous oxides will be referred to collectively as short-range ordered (SRO) materials.

In spite of their wide occurrence as intermediates in soil formation, allophane and imogolite were, until the second-half of the Twentieth Century, missed or ignored because of their virtual absence from XRD. When they were found to be important constituents of soils derived from volcanic ash (Taylor, 1933; Yoshinaga and Aomine, 1962; Abidin et al., 2007), researchers turned to a variety of methods more conducive to their identification, characterization, and quantification. These include selective dissolution by oxalic acid to quantify Si and Al, thermoanalytic methods to identify and quantify specific minerals, structural characterization by vibrational spectroscopy (IR and FTIR) (Farmer et al., 1977; Dahlgren, 1994), and electron microscopy

(Wilson, 1987). Short-range structural information has been obtained with solid-state NMR and x-ray absorption spectroscopy (XAS). Even the diffuse peaks in XRD patterns are useful to identify and quantify poorly crystalline materials (Cruz and Real, 1991). More recently, computer modeling has been employed to test proposed structures against spectroscopic data and to determine which structures give an energy minimum (Guimaraes et al., 2007; Creton et al., 2008; Zhao et al., 2009). The application of such methods to determine imogolite and allophane structure is discussed in the following sections.

23.1.2 Structure of Imogolite

Imogolite is a mineral with relatively constant chemical composition ($SiAl_2O_5 \cdot 2H_2O$), only six-fold coordination for Al, as many as seven x-ray diffraction peaks and two very broad "bands" (Table 23.1), and a distinctive tubular morphology observable under the electron microscope (Figure 23.1). Thus, imogolite has the major features of a crystalline mineral, but some consider it paracrystalline because each tube displays long-range order primarily in one dimension—along the length of the tube (Greenland, 1982). Diffraction patterns and electron micrographs, however, show that bundles of imogolite are aligned in an array with a repeat distance of around 2 nm, consistent with the diameter of the tubes (Figure 23.1; Cradwick et al., 1972). Thus, imogolite displays an added dimension of repeating units similar to layered aluminosilicates with regular stacking.

The Al in imogolite occurs in a gibbsite-like sheet and the Si is coordinated to three oxygen atoms and one hydroxyl group. The oxygen atoms are shared with the Al octahedra and the apical hydroxyls point toward the inside of the imogolite tube (Figure 23.2; Cradwick et al., 1972; Zhao et al., 2009). The separation distances between close-packed tubes are typically around 2.3 nm for natural and 2.7–3.2 nm for synthetic imogolite (Mukherjee et al., 2005) and the repeat distance along the gibbsite sheet (c-axis) is 0.84 nm (Wada and Yoshinaga, 1969).

[a] Also present in halloysite-like allophane.
[b] Present in all three allophanes.

Unraveling the structure of imogolite relies on spectroscopy and modeling. Infrared spectra give absorption bands indicative of both the gibbsite-like sheet and the orthosilicate anion. The Si–O stretching vibration at 960 cm^{-1} is consistent with unpolymerized orthosilicate groups and the OH-stretching bands are consistent with Al–OH and Si–OH structures described by Cradwick et al. (1972). In addition, the band at 348 cm^{-1} indicates that one hydroxyl of the octahedral Al sheet is replaced by the silica oxyanion. This band distinguishes imogolite and proto-imogolite allophane from other SRO aluminosilicates (Farmer et al., 1977). Molecular dynamics simulations that generate XRD patterns and vibrational spectra based on the Cradwick model compared favorably with the experimental ones (Creton et al., 2008).

Solid-state NMR spectra also support the above model for imogolite (Goodman et al., 1985; Wilson et al., 1986; He et al., 1995).
FIGURE 23.2 Polyhedral representations (left panel) and atomic structures (right panel) of (a) imogolite sheet and (b) imogolite nanotube with $N_\mu = 9$. (c) The local map of atomic structure. Si, Al, O, and H atoms and some representative bonds are indicated. (From Zhao, M., Y. Xia, and L. Mei. 2009. Energetic minimum structures of imogolite nanotubes: A first-principles prediction. *J. Phys. Chem. C* 113:14834–14837.)

The ^{27}Al-NMR spectra for various samples of synthetic and natural imogolite show little or no evidence of tetrahedrally coordinated Al (Figure 23.3). The ^{29}Si resonance line at -78 ppm of imogolite is consistent with Si bound to three Al–O and one OH group and serves to identify imogolite or proto-imogolite allophane in whole soils (Wilson et al., 1986).

The difference in size between natural and synthetic imogolite—2.3 vs. 2.7–3.2 nm—can be explained by density functional theory first-principle calculations that show two energy minima for the imogolite structure (Figure 23.4). The global minimum occurs with a gibbsite sheet consisting of 9 gibbsite units around the imogolite circumference and a local minimum with 12 gibbsite units (Zhao et al., 2009). These minima are consistent with the external diameters, circumferences, separation distances, and axial dimensions of imogolite determined experimentally by XRD and electron diffraction.

23.1.3 Structure of Allophane

Allophane refers to a group of SRO aluminosilicate clay minerals with no long-range order, only two diffuse XRD bands, and variable composition, generally ranging from 2:1 to 1:1 Al/Si molar ratio (Harsh et al., 2002). Endmember allophane would be completely disordered, but probably does not exist in nature (Fyfe et al., 1987). The further structural and chemical characterization of allophane found in natural environments has led to the identification of three major types of allophane. These have been tentatively named proto-imogolite allophane, halloysite-like (or defect kaolin) allophane, and hydrous feldspathoid allophane.

Proto-imogolite allophane (Al-rich allophane) has an Al/Si ratio close to 2, a gibbsite-like sheet of octahedrally coordinated Al, and orthosilicate groups sharing three oxygens with Al. Thus, proto-imogolite allophane has the same short-range order
FIGURE 23.3 ^{29}Si and ^{27}Al MAS NMR spectra of (a) Al-rich KiP allophane (<0.2 μm), (b) imogolite (KiG) film, (c) Si-rich PA allophane (<0.2 μm), (d) acid-oxalate-treated Si-rich PA allophane, and (e) hot 2% Na_2CO_3-treated Al-rich KiP allophane. *, Spinning side band (SSB). (From Hiradate, S., and S.-I. Wada. 2005. Weathering process of volcanic glass to allophane determined by 27 Al and 29 Si solid-state NMR. Clays Clay Miner. 53:401–408. Figure 3. Reproduced with kind permission of The Clay Minerals Society, publisher of *Clays and Clay Minerals*.)

as imogolite, but does not exhibit the tubular morphology. Instead, it first forms fragments of the imogolite structure, then, depending on solution conditions, forms imogolite or spherical allophane particles about 3.5 nm in diameter (Farmer and Russell, 1990). The NMR and FTIR spectra are nearly identical to those for imogolite (Figure 23.3). The XRD "peaks" are very broad and the pattern lacks several lines indicative of imogolite (Table 23.1).

According to one view, allophane with an Al/Si ratio near 1:1 probably has a structure that is closer to kaolinite or halloysite with defects in the tetrahedral sheet. Infrared spectra of Si-rich allophanes indicate the presence of polymerized silica tetrahedra and octahedrally coordinated Al (Parfitt et al., 1980; Farmer and Russell, 1990; Parfitt, 1990). Both IR and NMR spectra suggest that Si-rich allophanes often contain both the halloysite and imogolite structural units. The halloysite-like feature in the NMR spectrum is characterized by a broad ^{29}Si resonance around −86 ppm. Varying amounts of the two types of allophane could account for a large variation in the Al/Si ratios (from 2.5 to 1) when found in weathered pumice. Recent solid-state NMR (MacKenzie et al., 1991) and x-ray photoelectron spectroscopy (He et al., 1995) studies of the silica-rich allophane support the presence of both imogolite-like and defect kaolin-like structures.

Recent Al-K edge x-ray absorption near edge structure (XANES) analysis of Al-rich allophanes and imogolite, raises
FIGURE 23.4 Variation of the strain energy of imogolite nanotubes (cross section shown above) relative to imogolite sheet as a function of $N_μ$ (number of gibbsite units in the circumference). The error bars (<0.003 kJ mol^{-1}) are smaller than symbols. The bond length evolution of Al–O and Si–O bonds is plotted in the inset of this figure. (From Zhao, M., Y. Xia, and L. Mei. 2009. Energetic minimum structures of imogolite nanotubes: A first-principles prediction. J. Phys. Chem. C 113:14834–14837.)

questions about the above models. Specifically, Al-K-XANES shows only one octahedral Al site in both imogolite and allophane, regardless of Al/Si ratio (Ildefonse et al., 1994). In contrast, gibbsite and 1:1 clay minerals have two octahedral Al sites, while 2:1 phyllosilicates have one. This implies allophane and imogolite have a dioctahedral sheet that resembles that of pyrophyllite or mica rather than kaolinite.

Another Si-rich allophane with a significant, if not dominant, amount of tetrahedrally coordinated Al resembles a hydrous feldspathoid and contains no imogolite units. The basic structure appears to be that of a framework silicate with 1:3 Al for Si substitution. Octahedral Al neutralizes some of the negative charge generated by the substitution and may be associated with the inner surfaces of spherical particles. Particles isolated from a stream deposit in New Zealand are less than 3 nm in diameter and form in CO_2-charged water that increases in pH as it

degases (Wells et al., 1977; Childs et al., 1990). Similar particles can be synthesized in neutral to alkaline solutions and IR and NMR spectra are consistent with a hydrous feldspathoid structure (Farmer et al., 1979a; Wada and Wada, 1981). No –78 ppm resonance is observed in the ^{29}Si NMR spectra, as in imogolite, and the changes in NMR spectra with heating confirm that the hydrous feldspathoid allophane differs in structure from both proto-imogolite and kaolin defect allophane (MacKenzie et al., 1991; Ildefonse et al., 1994). Ildefonse et al. (1994) used ^{27}Al NMR and Al-K XANES to characterize Si-rich allophanes from soils and found them to be similar to those found in stream deposits, suggesting that Si activity in solution determines their formation.

23.2 Identification and Synthesis of Allophane and Imogolite

23.2.1 Imogolite Identification and Synthesis

Imogolite can be separated from soils and pumice deposits after removing material that strongly interacts with its surface. Pretreatment usually includes a dithionite–citrate–bicarbonate extraction to remove iron oxides and hydrogen peroxide to remove organic matter. Neither significantly dissolves nor alters imogolite or allophane. Following pretreatment, ultrasonic dispersion of the suspended pumice or soil at low pH (e.g., pH 4 HCl) separates imogolite from phyllosilicate clay minerals. As discussed in Section 23.4.1, imogolite surfaces are positively charged in acid solutions and form stable suspensions, while the 2:1 phyllosilicates flocculate at low pH. Further concentration of SRO materials is accomplished by separating the <0.08 μm fraction because average allophane and imogolite particle sizes are much less than those of the 1:1 phyllosilicates. Of course, no purification procedure is ideal; unwanted minerals and some alteration of the target material will always be present.

While spectroscopic methods elucidate imogolite structure and often aid in quantitative methods, electron microscopy is the most reliable indicator of its presence in soils or successful synthesis in the laboratory. Both synthetic imogolite and that isolated from a pumice bed show long, bundled tubes (Figure 23.1), whereas, imogolite isolated from a forest soil is somewhat more fragmented (Su and Harsh, 1996).

Refluxing an acidic solution with millimolar concentrations of aluminum perchlorate and tetraethyl orthosilicate for 5 days at 95°C produces imogolite nearly identical to the natural material isolated from soils or pumice except for the larger diameter mentioned above (Farmer et al., 1983). The larger diameter may be due, in part, to the high-temperature synthesis, because imogolite prepared at room temperature has a diameter of about 23 Å (Wada, 1987). Levard et al. (2009) synthesized imogolite from decimolar concentrations of Al and Si, perhaps opening the door to manufacture of large quantities of material.

23.2.2 Allophane Identification and Synthesis

Separation of allophane from natural deposits, including soils, is similar to that of imogolite. Allophane is positively charged in a low pH solution and will form a stable suspension along with imogolite when ultrasonically dispersed. The same pretreatment to remove iron oxides and organic material applies. With allophane, however, separation from imogolite is possible in principle because it is negatively charged in alkaline solutions where imogolite flocculates.

After separation, one can discern allophane in electron micrographs, but it is far less distinctive than imogolite (Figure 23.4). It generally occurs as an amorphous mass of material coating other particles. Often the spheroidal morphology is evident in the Al-rich allophane. The spheroids of Al-rich allophane form aggregates that do not disperse easily. Damage from the electron beam is rapid and care must be taken to obtain good micrographs.

Like imogolite, allophane is synthesized from millimolar solutions of Al and monomeric Si(OH)$_4$. Allophane can be precipitated rapidly from solutions at room temperature. Methods, including heated synthesis, have been developed to precipitate allophane from concentrated solutions—10–100 mM (Ohashi et al., 1998; Montarges-Pelletier et al., 2005). The Al/Si ratio and pH of the matrix solution determine the nature of the products. Al-rich allophane forms at room temperature from an acidic Al and orthosilicate solution with Al/Si ratio near 2:1. The presence of Ca and Mg ions favors allophane formation over imogolite, whereas Na and K do not (Abidin et al., 2007). Because the acidic environment keeps Al in octahedral coordination, decreasing the Al/Si ratio while keeping the pH below neutral probably favors the defect kaolinite structure. Between pH 6 and 7, the hydrous feldspathoid structure predominates with the proportion of tetrahedral Al increasing as the Al/Si ratio decreases (Farmer and Russell, 1990). This structure exists in natural alkaline environments, including the Silica Springs deposit in New Zealand (Wells et al., 1977) and many soils (Childs et al., 1990; Ildefonse et al., 1994). Farmer and Russell (1990) reviewed the synthesis and occurrence of imogolite and the three types of allophane described here.

23.3 Occurrence of Imogolite and Allophane in Natural Environments

Allophane and imogolite tend to be associated with volcanic ash deposits and soils derived from volcanic debris, because the rapid release of Al and Si from materials such as volcanic glass results in the precipitation of SRO aluminosilicates. The Kitakami pumice beds in Japan have long been a source of relatively pure separates of both allophane and imogolite and are among the most studied of the naturally occurring SRO materials, including the KiG imogolite in Figure 23.3 (Miyauchi and Aomine, 1966; Wada and Matsubara, 1968; Yoshinaga, 1968; Yoshinaga et al., 1973). Imogolite was first identified in Ando (dark-colored) soils of Japan (Yoshinaga and Aomine, 1962) and allophane was found to give them many of their unique properties. Since then, SRO aluminosilicates have been identified in soils derived from many parent materials, including sandstone, gneiss, granite, and basalt (Harsh et al., 2002). In basalt, ferrihydrite, a poorly crystalline

iron oxide, often occurs in addition to allophane and imogolite. Nevertheless, the largest concentrations of SRO aluminosilicates occur in deposits of volcanic tephra and soils developed therein. Soils derived from volcanic tephra occur all over the world with well studied examples from New Zealand (Taylor, 1933; Wells et al., 1977; Parfitt, 1990), Chile (Vicente and Besoain, 1961; Besoain, 1969; Nissen and Kuehne, 1976; Besoain and Gonzalez, 1977; Floody et al., 2009), and the Cascade Range of North America (Ugolini and Dahlgren, 1991). A large deposit of allophane—more than 4000 km^2 and 16 m thick—was recently discovered in Ecuador and may be a source for commercial allophane (Kaufhold et al., 2009, 2010). McDowell and Hamilton (2009) report that SRO aluminosilicates are probably present on Mars and interfere with quantification of phyllosilicates on the surface.

The key factor in the formation of allophane and imogolite in soil is sufficient Al and Si in solution. Thus, conditions that lead to rapid weathering of primary minerals, such as high rainfall and low pH, favor their formation. Both imogolite and Al-rich allophane tend to dominate at low pH where Al/Si is high, whereas halloysite and/or Si-rich allophanes form when soluble Si is high ($>10^{-3.45}$). As a result, low rainfall or xeric-moisture regimes, concentrating soluble silica, have been observed to favor halloysite formation at the expense of allophane and imogolite (Parfitt and Wilson, 1985; Singleton et al., 1989; Takahashi et al., 1993). Noncrystalline minerals are found in Andisols, Inceptisols, Entisols, Spodosols, and Ultisols. Generally, allophane and imogolite occur in horizons where organic matter is low so that Al exists in inorganic complexes. Al-humus complexes, which give soils many of the same properties attributed to allophanic soils, often dominate organic and A horizons, particularly in forested soils (Dahlgren et al., 2004). Complexation of Al by organic acids and humic materials inhibits SRO aluminosilicate formation indicating that free Al^{3+} or Al-hydroxy complexes may be required.

Short-range ordered materials are generally less stable than their crystalline counterparts, particularly kaolinite. Their rapid formation results because the interfacial energy difference between mineral surfaces and an aqueous solution slows nucleation. Poorly crystalline surfaces have lower surface tensions and nucleate more easily, that is, at a lower saturation index than a crystalline mineral of similar composition. As a result, allophane and imogolite are often found as precursors to kaolinite in weathering soil profiles and may serve as templates for its heterogeneous nucleation (Steefel et al., 1990).

Quantification of SRO aluminosilicates in soils is achieved by selective chemical extraction and solution analysis of Al and Si (Dahlgren, 1994). Commonly, one extracts the soil first with Na-pyrophosphate, which effectively extracts Al and Fe from soil organic complexes, but dissolves little from the inorganic fraction. Then, an acid ammonium oxalate solution (0.2 M, pH 3) selectively dissolves allophane, imogolite, and poorly crystalline iron oxides such as ferrihydrite. Subtracting the organically complexed from the oxalate-extracted, gives the SRO-associated Al and Fe. Dividing this SRO Al value by the oxalate-extractable Si provides the average SRO Al/Si ratio (Parfitt and Wilson, 1985). A ratio near 2:1 suggests a soil dominated by imogolite

and proto-imogolite allophane whereas a smaller value indicates Si-rich allophane is present. Embryonic halloysite may also partially dissolve in the oxalate solution (Wada and Kakuto, 1985). Ratios greater than 2:1 may occur when other labile sources of Al are present, such as hydroxy-Al interlayers in clay minerals.

23.4 Surface Charge Characteristics of Short-Range Ordered Aluminosilicates and Variable-Charge Soils

23.4.1 Surface Charge Determination

23.4.1.1 Operational Definitions

Two major sources of surface charge on SRO aluminosilicates will be considered here, that is, permanent structural charge (σ_o) from isomorphic substitution of Al in Si tetrahedra and variable surface charge due to ion association at surface hydroxyl groups (Sposito, 2004). Ion associations with surface hydroxyls include complexed protons (σ_H), inner-sphere complexes with ions other than H^+ (σ_{IS}), and outer-sphere complexes (σ_{OS}). A charge balance equation can be written as follows:

$$\sigma_P = \sigma_o + \sigma_H + \sigma_{IS} + \sigma_{OS} = -\sigma_D \qquad (23.1)$$

where

  σ_P represents the particle charge or total charge from all sources

  σ_D is the diffuse layer charge that consists of the net charge from the swarm of hydrated ions around the particle

The proton charge on variable-charge surfaces is determined by potentiometric titration with H and OH, which adsorb to surface silanol ($\equiv Si-OH$) or aluminol ($\equiv Al-OH$) groups. Relative proton adsorption is easy to determine from the difference between added and remaining protons in solution, but the absolute proton charge on the surface is not evident because the initial charge, before titration, is not known. The point of zero net proton charge (PZNPC) is often estimated by the point of zero salt effect (PZSE)—the pH at the crossover point of three or more titrations at different background salt concentrations. If the background salt does not form inner-sphere complexes, only the proton charge is determined in the titration. The proton charge is more reliably determined by plotting the net adsorbed ion charge ($\sigma_{IS} + \sigma_{OS} + \sigma_D$) against proton charge (σ_H) (Chorover and Sposito, 1995). The slope should be −1 and the x- and y-intercepts equal to σ_o. The PZNPC is then the pH where ($\sigma_{IS} + \sigma_{OS} + \sigma_D$) = −$\sigma_o$.

Inner-sphere, outer-sphere, and diffuse layer cations and anions balance the total negative and positive charge on the surface. Thus, the point of zero net charge (PZNC) can be determined by ion adsorption across a range of pH in an electrolyte, such as NaCl, whose ions do not form inner-sphere complexes with the aluminol or silanol groups. Finally, electrophoretic mobility provides information about the tendency for ions to

form outer-sphere complexes with allophane and imogolite. Their mobility when suspended in an aqueous solution subjected to an electric field depends on the ionic strength of the solution and the nature of the surface complexes. The isoelectric point is the pH where the particles are stationary in the field and is an estimate of the PZC—the point where $\sigma_D = 0$.

With all Al in imogolite and proto-imogolite allophane in octahedral coordination, no structural charge arises from isomorphic substitution. Gustafsson (2001), however, proposed that structural charge could arise from differences in Al–O bond valences leading to a weak positive charge on outer tube walls and negative charge in tubular pores. This hypothesis was later supported by quantum mechanical calculations of charge distribution in imogolite (Guimaraes et al., 2007). The Si-rich allophane, on the other hand, has structural charge arising from Al for Si substitution. However, Su et al. (1992) found in synthetic allophanes of this type that structural charge from tetrahedral Al was not completely balanced by exchangeable cations. In this case, it was hypothesized that Al present as hydroxy complexes or polymers balanced much of the negative σ_o.

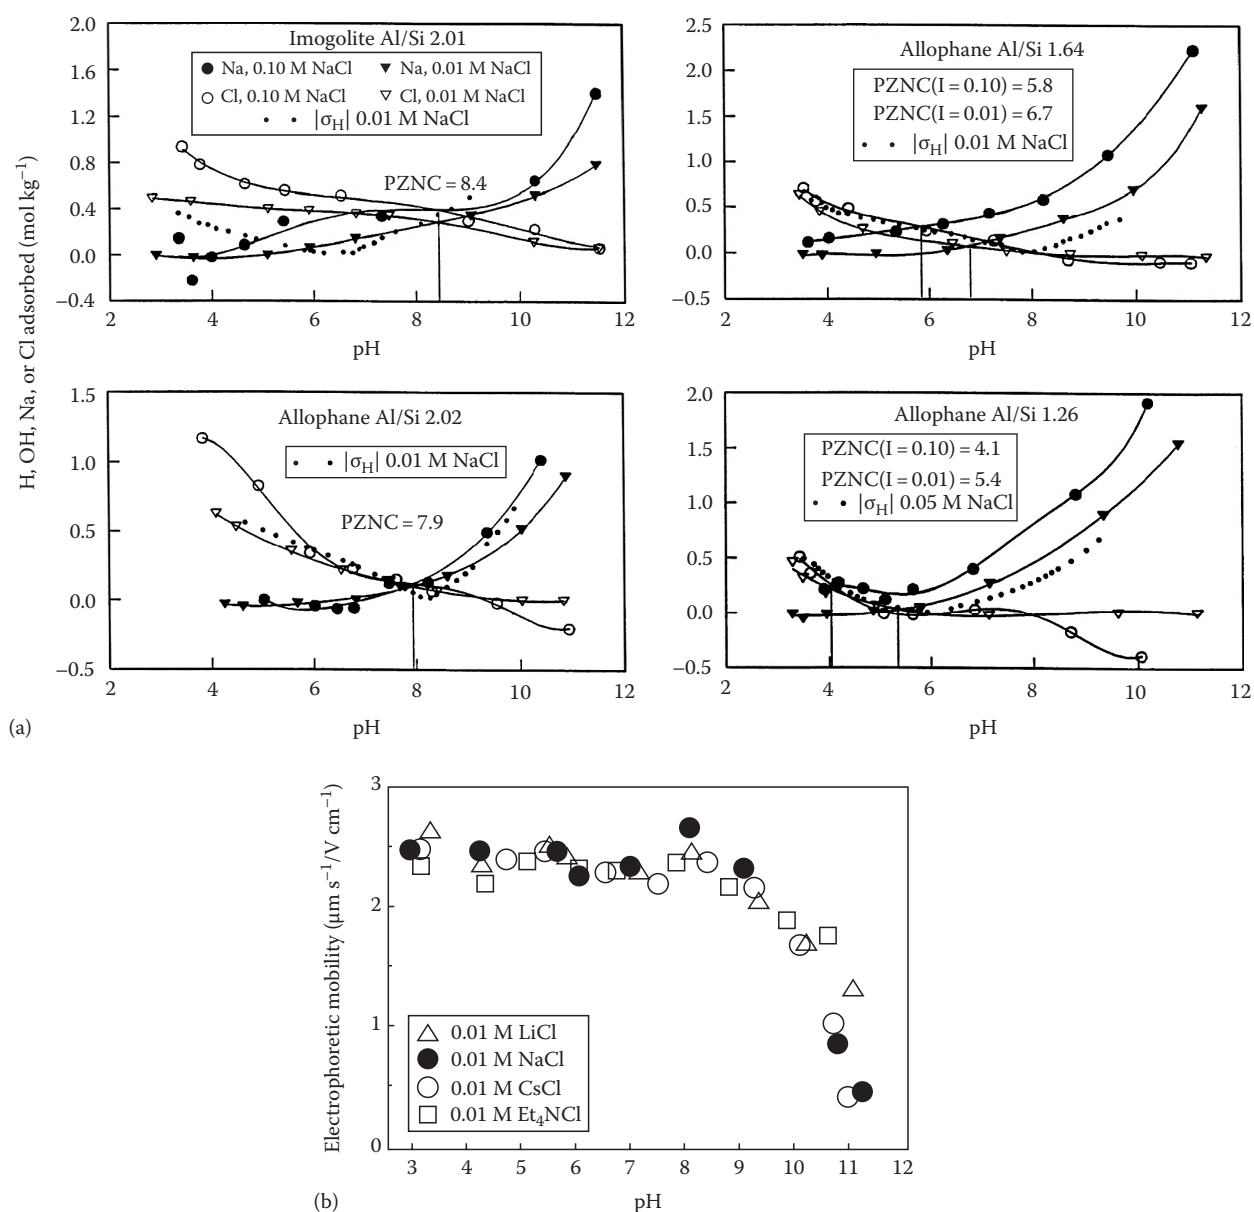
The charge characteristics of imogolite and some synthetic allophanes as determined by these methods are summarized in Figure 23.5 and Table 23.2. Because the PZNC and PZSE values of imogolite and Al-rich allophane are all greater than 6, these


FIGURE 23.5 Charge properties of synthetic imogolite and allophane determined by (a) potentiometric titration and ion adsorption (From Su, C.M. et al., *Clays Clay Miner.*, 40, 280, 1992, Figure 1. Reproduced with kind permission of The Clay Minerals Society, publisher of *Clays and Clay Minerals*.) (b) electrophoretic mobility (From Harsh, J.B., S.J. Traina, J. Boyle, and Y. Yang. 1992. Adsorption of cations on imogolite and their effect on surface-charge characteristics. Clays Clay Miner. 40:700–706, Figure 4. Reproduced with kind permission of The Clay Minerals Society, publisher of *Clays and Clay Minerals*.)

		PZNC in NaCl			
Material	Al/Si	0.10 M	0.01 M	PZSE	PZC
Imogolite	2.0	8.4	8.4	6.5	>10
Allophane	2.0	7.9	7.9	8.3	10
Allophane	1.6	5.8	6.7	7.7	9
Allophane	1.2	4.1	5.4	5.9	7.6

materials impart positive charge in acid soils. The Si-rich allophanes may be either positively or negatively charged depending on soil pH. The Si-rich allophanes also have a PZSE greater than the PZNC, another indicator that permanent negative charge exists in these materials as a result of Al for Si substitution. Imogolite has a PZSE greater than its PZNC, constant adsorption of Cl over a large pH range, and an isoelectric point above pH 10 (Harsh et al., 1992; Tsuchida et al., 2005), all of which might be due in part to cation distribution inside imogolite tubes as well as structural charge distribution from bond valence differences as discussed above (Gustafsson, 2001).

23.4.2 Interaction with Anions and Cations

Inner-sphere complexation of anions on allophane and imogolite is common. Phosphate, fluoride, citrate, borate, arsenate, and selenite are known to form inner-sphere complexes with SRO aluminosilicates. This reaction contributes to σ_{IS} and can shift the points of zero charge (PZCs) of the material. As a result, more negative charge is likely in the presence of these anions, particularly in acid soils. Caution should be used in interpreting any strong sorption as surface complexation. Veith and Sposito (1977) and Su and Harsh (1993) showed that phosphate and fluoride, respectively, may react with SRO aluminosilicates to form new solid phases. Boron may substitute into tetrahedral sites in coprecipitation with allophane (Su and Suarez, 1997).

In soils containing allophane and imogolite, strong interaction with phosphate can lead to deficiency of this macronutrient in crops. Calcium silicate can be added to such soils to compete for sorption sites and enhance phosphate availability. The ability of SRO materials and allophanic soils to adsorb anions by ligand or anion exchange has led to suggestions that they be used to remove contaminants such as phosphate, selenium, technetium, glyphosate, chromium, arsenic, and iodine from wastewaters (Wells and Parfitt, 1987; Gu and Schulze, 1991; Babel and Opiso, 2007; Gimsing et al., 2007; Hopp et al., 2008; Opiso et al., 2009; Ballantine and Tanner, 2010).

Many trace metals and metalloids form surface complexes with aluminol and silanol groups as evidenced by extensive studies on silica and aluminum oxides; however, fewer studies have been performed on SRO aluminosilicates or soils containing them. One study of metal adsorption to a soil dominated

by allophane and imogolite in the clay fraction showed the following order of decreasing affinity, which is quite similar to the selectivity of aluminol groups for divalent metals (Abd-Elfattah and Wada, 1981):

$$Pb > Cu > Zn > Co \approx Cd > Mg \approx Ca$$
As on Al oxides, Pb, Cu, Zn, and Co appear to form inner-sphere surface complexes, whereas Cd, Ca, and Mg are held by electrostatic forces (Clark and McBride, 1984; Yuan et al., 2002). Alkaline earth and alkali metals, halide anions, NO_3, SO_4, and ClO_4 will generally exist as outer-sphere complexes or in the diffuse layer of allophane and imogolite. Adsorption of exchangeable cations on allophanic soils appears to be similar to that on soils dominated by smectites (Nakahara and Wada, 1994). Highly selective K exchange on Andisols has been reported (Espino-Mesa and Hernández-Moreno, 1994), but this could result from trace amounts of illitic minerals or alunite formation in addition to reactions with allophane or imogolite. Allophanic soils do seem capable of adsorbing large amounts of nitrate below the root zone, presumably through interaction with SRO aluminosilicates (Maeda et al., 2008). Circumstantial evidence exists for specific adsorption of Cl on imogolite, as discussed above, but this issue has not been resolved and is not consistent with electrophoretic measurements (Figure 23.5).

The interaction of allophane and allophanic soils with organic matter (discussed in the following section) also affects the surface charge and sorption properties of the materials. Organic matter can be expected to increase the negative charge on minerals dominated by aluminol surface groups because of the carboxylate groups of humic materials. Treatment of allophanic materials and soils with hydrogen peroxide to remove organic matter increases the PZC (Escudey et al., 1986) and decreases phosphate sorption (Mora and Canales, 1995), respectively. Conversely, adding iron oxides increases the PZC of allophane, rendering the surface more positively charged (Escudey and Galindo, 1983). Iron oxides may react selectively with silanol groups, which have an acid PZNPC. The PZNPCs of Fe and Al oxides, on the other hand, are greater than 6.

23.5 Interaction of Allophane and Imogolite with Other Soil Constituents

23.5.1 Organic Matter and Iron Oxides

The term "Andisol" comes from the Japanese words *ando* and *sol*, meaning dark-colored soil. The dark color comes from the fact that soils formed from volcanic debris are often high in organic matter, especially in surface horizons. Noncrystalline materials may play a role in organic matter retention through one or more mechanisms. First, humic substances adsorb strongly to imogolite and allophane (Parfitt et al., 1977; Parfitt, 2009) and sorption is possibly responsible for inhibiting degradation (Basile-Doelsch et al., 2005; Schneider et al., 2010). Second, reactive Al released

from SRO materials complexes with humic and fulvic acids and leads to precipitation and/or inhibition of degradation (Boudot, 1992; Wada, 1995; Matus et al., 2008). Finally, SRO materials may enhance the "humification" of soil organic carbon by facilitating bonding reactions or molecular assemblages (Gonzalez-Perez et al., 2007; Fukushima et al., 2009). In the presence of hydrogen peroxide, allophane associated with Fe may catalyze the degradation of organic materials, including xenobiotics, by Fenton reactions (Garrido-Ramirez et al., 2010).

Reaction with organic matter may give soils containing SRO aluminosilicates an important role in carbon sequestration. If these materials are instrumental in increasing the residence time of organic matter in soils, then preserving the soils containing them may be beneficial in order to reduce emission of greenhouse gases such as CO_2. Dahlgren et al. (2004) stated that 0.8% of the world's soils are allophanic and that they contain 5% of the global soil carbon. In his excellent review of the biogeochemistry of allophane and imogolite, Parfitt (2009) points out that the stabilization of organic matter is partially maintained as forests are converted to pasture, but does not apply to fresh organic matter or plant-derived material. The recalcitrant carbon originates from microbial byproducts, is stabilized slowly, and persists for thousands of years.

23.5.2 Water

Both a high specific surface area and a high value of the relative microporosity characterize allophane. The latter probably
FIGURE 23.6 Stability relations for proto-imogolite (Lumsdon and Farmer, 1995), Si-rich allophane (HAS_B), gibbsite, and microcrystalline gibbsite. (From Dobrzynski, D. 2007. Chemistry of neutral and alkaline waters with low Al^{3+} activity against hydroxyaluminosilicate HASB solubility. The evidence from ground and surface waters of the Sudetes Mts. (SW Poland). Aquat. Geochem. 13:197–210.)

(Two-ion parameter $log[Al^{3+}] + 3pH$ versus $log[H_4SiO_4]$ in waters with $log[Al^{3+}] < -10$ (size—188 samples). Solubility lines for amorphous $Al(OH)_3$ and SiO_2 forms plotted at 7°C, after solubility constant for gibbsite ($log\ K^{25} = 8.11$), microcrystalline gibbsite ($log\ K^{25} = 9.35$), and $Al(OH)_3(a)$ ($log\ K^{25} = 10.8$) calculated using the van't Hoff equation. Solubility constant $log\ K^7$ for chalcedony and amorphous SiO_2 calculated using the analytical expression after Nordstrom et al. (1990).

Proto-imogolite solubility line at 7°C plotted for the reaction:

$$0.5Al_2SiO_3(OH)_4(s) + 3H^+ = Al^{3+} + 0.5H_4SiO_4 + 1.5H_2O$$
($log\ K^{25} = 7.02$, $\Delta H = -96.8\ kJ\ mol^{-1}$) after Lumsdon and Farmer (1995).

HASB solubility line for the reaction:

$$Al_2Si_2O_5(OH)_4 + 6H^+ = 2Al^{3+} + 2H_4SiO_4 + H_2O\ (log\ K^7 = 14.0 \pm 0.7)$$

with uncertainty of solubility plotted.)

results largely from micropores formed from aggregates of particles because the porosity decreases with the shrinkage observed on drying. As a result, water retention in allophanic soils is very high at a given water potential compared to soils dominated by crystalline clays. This, in part, accounts for the high productivity often seen in forested soils high in SRO materials (Martini and Luzuriaga, 1989; Nizeyimana, 1997). Macroporosity is also high in most allophanic soils resulting in good infiltration and hydraulic conductivity. The latter parameter has been found to decrease significantly in soils at pH values where allophane is known to disperse easily (pH = 3 and 11) (Nakagawa and Ishiguro, 1994).

The aqueous solubility of imogolite and proto-imogolite allophane shows them to be less stable than kaolinite at soluble silica activities expected in natural soils (Farmer et al., 1979b; Percival, 1991; Su and Harsh, 1994; Gustafsson et al., 1998; Su and Harsh, 1998; Wada and Kakuto, 1999). However, imogolite and proto-imogolite allophane are more stable than halloysite at low Si activity (Su and Harsh, 1994). Thermodynamically, halloysite is stable relative to imogolite at a log $Si(OH)_4$ activity greater than about −3.5. Halloysite is more stable than allophane at a lower Si activity, but allophane formation in preference to halloysite is commonly observed in soils at log $(H_4SiO_4) > −3.45$ (Singleton et al., 1989). This incongruity may indicate that soil solution analyses performed at a later date may not be relevant to the time of mineral formation. Kinetic considerations may favor the SRO materials relative to halloysite; this certainly is true relative to kaolinite. The solubility constants determined for imogolite and allophane may be incorrect or the solid phases controlling the solubility of Al, such as gibbsite or Al complexed with organic matter, may not be well understood (Gustafsson et al., 2001). Current solubility data seem to support different solubility constants for synthetic and soil imogolite—log K_{syn} = 6.05 and log K_{soil} = 6.60 at 25°C for the reaction:

$$0.5(HO)_3Al_2O_3SiOH(s) + 3H^+ = Al^{3+} + 0.5H_4SiO_4 + 1.5H_2O$$

(23.2)
The solubility of minerals in soils is complicated by nonequilibrium conditions, difficulty in speciating soluble ions, particularly Al, and determination of controlling phases (Gustafsson et al., 2001). Nevertheless, the chemistry of soil solutions and natural waters may often be determined by these rapidly formed, but persistent, poorly crystalline materials (Dobrzynski, 2007) (Figure 23.6).

Soil Biology and Biochemistry: Soil Biology in Its Second Golden Age

E.A. Paul
Colorado State University

Paolo Nannipieri
University of Florence

SOIL BIOLOGY, THE STUDY OF soil organisms and their processes, discusses the most abundant living organism on earth. The early characterization of visible fungi, such as that in the *Theatrum Fungorium*, published in 1675 and Leeuwenhoek's microscopic investigation of bacteria during the same century, represented the initial creation of this field from an observational viewpoint. The study of organisms and soil processes started with Darwin's explanation of the role of earthworms in soil formation. The studies in the mid-nineteenth century of nitrogen transformations by Warington, Lawes, and Gilbert (Paul, 2007) represented the beginnings of scientific soil process studies. However, the true recognition of this field occurred during the period of 1890–1910 when organisms carrying out the processes necessary for decomposition and nitrogen and sulfur cycles were described by Beijerinck and Winogradsky (Waksman, 1932). That period has been named the "golden age" of soil microbiology (Waksman, 1932). The advent of tracers in the mid-twentieth century allowed the measurement of the dynamics of the processes in situ. Molecular techniques that were adapted to soils came about 100 years after the first golden age with the initial paper of Torsvik (1980). Great advances in molecular techniques, for both the study of biological nuclear materials and for modern studies of organic matter structure, have occurred during the last 20 years. The soil biology chapters in this book describe these advances in the classification of the soil organisms and the measurement of their processes. The progress and advancement of our knowledge has been so profound that we can depict this section as the "second golden age" of soil biology.

The soil bacteria and archaea, ranging in size from 0.2 to a few microns in diameter, have populations between 10^9 and 10^{10} organisms per gram of soil. The smallest soil biota include the submicroscopic viruses and prions that require living cells for reproduction. They exist in soil in numbers equivalent to the bacteria. The larger, filamentous fungi often have a similar biomass to that of the bacteria, but in examples such as the *Armillaria*, associated with multiple tree roots they can exist as a single organism with an area of several hectares (Thorn and Lynch, 2007). The recently discovered archaea, with their special cell structures, in addition to the predatory protozoa, comprise the remainder of the soil microorganisms that carry out the majority of nutrient transformations in soil. The archaea and bacteria are characterized by a lack of a nucleus and other structures, such as mitochondria, yet these are the only organisms that contain the complex enzyme systems for N_2 fixation, nitrification, methane oxidation, and reduction, and the inorganic sulfur and metal transformations (Killham and Prosser, 2007). Although these are the earth's oldest living inhabitants, their small size and lack of morphological diversity had made their study difficult until the advent of the soil molecular studies (Torsvik, 1980). While less in number and biomass, the soil animals, or fauna, play significant roles in soil mixing, or bioengineering, and the consumption of microorganisms (Coleman and Crossley, 1996; Lavelle et al., 2004). The total soil biota comprise 2%–5% of the soil organic carbon content and 4%–8% of its

nitrogen (Bardgett et al., 2005). Because of the close interaction of the living cells with external enzymes and the soil mineral matrix, soil has been often described as a self-controlled living entity with many similar characteristics over many parts of the world (McGill, 2007). The factors controlling biochemical reactions and those affecting population and soil organic matter turnover are similar. Thus, while individual soils show the interaction of these factors with their environment (Morris and Blackwood, 2007), many advances will be made by studying the unifying principles (Fierer et al., 2009) that control soil biology on a global basis.

Soil biochemistry, a second component of soil biology, refers to both the physiology and chemistry within the living cells that catalyze life's functions, as well as the activity of external enzymes. Important biological molecules (i.e., nucleic acids and proteins, including extracellular enzymes) can be adsorbed by surface-reactive particles (i.e., clays), thus becoming protected against the degradation reactions of proteases and nucleases without losing their activity. The capacity of the immobilized enzyme to catalyze the target reactions, and the availability of the extracellular adsorbed DNA to be taken up by competent bacterial cells to be incorporated into the bacterial genome, is strongly affected by the soil matrix consisting of silts, clays, and sesquioxides (Stotzky, 1986; Nielsen et al., 2006; Pietramellara et al., 2009). This section of the handbook contains chapters on soil biota, the status and origin of soil enzymes, and the meaning of current enzyme assays. Organisms that inhabit soil carry out the nutrient transformations that make life possible (Coleman and Crossley, 1996). As decomposers of the products of photosynthesis and thus plant growth, the soil biota complete the carbon cycle. The current global change problems result from a disturbance of a very old steady state between photosynthesis and decomposition. Decomposition proceeds at a slightly smaller rate than photosynthesis (Stevenson, 1994) resulting in a buildup of the soil organic matter, which is so essential to sustainable agriculture, ecosystem functioning, and carbon sequestration in global change. Soil at $15–20 \times 10^{15}$ g C has twice as much C as the atmosphere. The recent utilization of photosynthesized C stored in coal and oil deposits over millions of years, the cultivation of soils, and the disturbance of ecosystems, such as occurs in fires, is upsetting this steady state and has caused our current climate change problems by returning, rather than fixing, more CO_2 into the atmosphere (Ojima, 1992). For a long time, it has been hypothesized that recalcitrance of organic substrates in soil was the main driver of soil organic matter survival in the long term. Clear analytical evidence now shows that inherently recalcitrant plant compounds such as *n*-alkanes and lignins turn over faster than bulk soil organic carbon (Marschner et al., 2008).

Nitrogen is as important to life and soil organic matter formation as is carbon. In addition, many of the same organisms that decompose carbon also mineralize nitrogen.

Nitrogen also undergoes numerous inorganic reactions, such as nitrification–denitrification and N_2 fixation, which are primarily carried out by bacteria and archaea that complete the complex nitrogen cycle and make plant growth possible

(Norton, 2008). Where N is present in excess quantities, these reactions can also cause water pollution and the release of greenhouse gases that are much more potent than carbon dioxide.

The great diversity of soil biota, in addition to the importance of their metabolism, their large numbers, and the possible significance of still-to-be-identified soil organisms, increase the value of the study of soil biology from a pure science–natural history standpoint. This diversity also contributes to ecological stability (Wall, 2004). Due to the wide variety in both number and type of decomposing organisms, the loss of one or two species may not affect this process. However, specialized processes, such as nitrification carried out by a few specialized bacteria, can be affected and would only be more sensitive to disturbance. The vast competitiveness and number of organisms assure the breakdown of most organics, whether natural or man-made, and also serve in self-cleansing the soil of potential disease-carrying organisms. Even so, soil is not infallible. Overloading with man-made chemicals and toxic organisms can lead to a breakdown of this self-cleansing characteristic.

The field of soil biology has both greatly benefited from and contributed to present breakthroughs in molecular biology. These techniques are now available to a wide range of ecologists, microbiologists, and soil scientists, and allow for the characterization of previously unknown organisms, such as the participation of archaea in nitrification (Nicol and Schleper, 2006). Process-specific probes allow for the determination of genes encoding for specific processes, such as those described in this book for the uptake of phosphorus by mycorrhiza. The study of proteomics allows for the measurement of the compounds actually involved in the reactions and will tie new studies with the rich classical literature on soil enzymes (Nannipieri and Paul, 2009). It is now possible to study microbial growth by tying stable-isotope probing or metagenomic measurements (which include the molecular structure) to more classical microbial growth and incubation studies, providing access to a great amount of information. Many factors affect gene expression in soil and the study of DNA by itself is not sufficient. Examples of the study of the presence and expression of genes, in addition to the characteristics of the expressed proteins, are now available (Nannipieri and Paul, 2009). While many reactions in soil have been characterized, many new reactions and organisms are being discovered; for example, the organisms that are involved in anaerobic metabolism of methane and sulfur (Section 26.4). The Anammox bacteria that oxidize ammonia to N_2 under anaerobic conditions in the presence of nitrite–nitrate are but one example. They have been found in biofilms of oxygen-limited reactors (Jetten, 2001), and it is reasonable to hypothesize their presence in soil under anaerobic conditions (Nannipieri and Paul, 2009).

It is the intent of the author's of this book to integrate new breakthroughs with the vast amount of information from classical literature such that a true foundation for even greater advances in knowledge is established. It provides numerous examples of the study of the presence and expression of genes, as well as the characteristics of expressed proteins. The description of viruses, based on molecular techniques, present an integrated analysis of their numbers and classification. Molecular methods for the study of archaea, bacteria, and fungi have richly contributed to our new knowledge of the vast array of organisms in soil. At least 90% of the bacteria and archaea active in soil are yet to be identified, and the fungi and nematodes are being reclassified. Process probes have revolutionized our understanding of the functioning of the important mycorrhizal organisms and their associations with plants. The development of new techniques, such as those for the rapid throughput of molecular information in pyrosequencing and the combination of tracers and molecular techniques as used in stable-isotope probing indicates that more advances are forthcoming. Soil biology can only progress based from an integrated knowledge of all organisms involved and an increased understanding of the methods of analysis, their strengths, and limitations (Andren et al., 2008). In spite of the diversity in both soil processes and soil organisms, there is now also a recognition of the great unity in the biotic and abiotic controls that affect both the organisms and their processes. This section has brought together both the recent knowledge and the fundamental unifying principles in a readable format with good reference to both classical and modern literature. It should comprise both an excellent introduction to the soil biota, as well as a good indication of potential progress in the future.

24.1 Viruses in Soil Ecosystems

Kurt E. Williamson

Sharath Srinivasiah

K. Eric Wommack

24.1.1 Introduction

Viruses are obligate genetic parasites that require the replication machinery of a cellular host in order to complete their own reproductive cycles. Outside of host cells, viruses exist as particles consisting of a nucleic acid genome surrounded by a protein coat, known as a *capsid*. Depending upon the specific virus, the genome may comprise DNA or RNA, which in turn may be double or single stranded. Viral capsids may be icosahedral, spherical, pleomorphic, filamentous, or rod shaped. Virus structure may also include additional features such as lipid envelopes, apical spikes, and tails (Figure 24.1). Soils provide an incredible range of niches housing a diverse array of organisms, leading to a similarly diverse representation of viruses that parasitize these organisms. Soils have been shown to contain plant viruses (Fillhart et al., 1998; Delogu et al., 2003), insect viruses (Fuxa, 2004; Christian et al., 2006), fungal viruses (Melzer and Bidochka, 1998), animal viruses (Duboise et al., 1979; Santamaria and Toranzos, 2003; Pourcher et al., 2007), and bacterial viruses (also known as bacteriophages or simply "phages") (Yin et al., 1997; Ashelford et al., 1999a, 2000, 2003; Keel et al., 2002; Williamson et al., 2003, 2005, 2007).

Historically, the study of viruses in soil has focused on economically significant pathogens of plants, animals, and insects. A large body of research is available concerning the fate and transport of land-applied human viral pathogens through wastewater or biosolids (Duboise et al., 1979; Santamaria and Toranzos, 2003). However, more recent data indicate that the majority of naturally occurring soil viruses are tailed phages with dsDNA genomes (Williamson et al., 2005). This is consistent with the overwhelming abundance of bacteria relative to other potential host organisms in soil ecosystems.
FIGURE 24.1 Common morphologies of soil viruses. (a) *Podoviridae*, icosahedral capsid symmetry with short, noncontractile tail; (b) *Siphoviridae*, icosahedral capsid symmetry with long flexible, non-contractile tail; (c) *Myoviridae*, prolate icosahedral capsid symmetry with long, contractile tail; (d) rendering of *Myoviridae* particle attached to host cell, tail contracted. Tail structures are used in host recognition, attachment, and infection.

24.1.2 Virus Life Cycle

In order to appreciate the influences that viruses can exert within the soil ecosystem, it is important to understand the modes through which viruses replicate. Most viruses replicate through one of two major life cycles: acute or persistent. Our current understanding of viral replication is based largely upon studies of bacteriophages; thus, while the terms "phage" and "virus" are often used interchangeably, it is important to remember this distinction.

The acute pathway, also known as lytic replication in phages, is carried out by *virulent* viruses. Acute viral infections are characterized by rapid production of intracellular virus particles followed by host cell lysis and release of progeny virions (Figure 24.2). Acute infections tend to quickly eliminate local populations of susceptible hosts, and extracellular virus particles must survive long enough to propagate infection if the virus strain is to remain successful. By contrast, persistent infections, also known as *lysogenic* replication among phages (Figure 24.2), are carried out by *temperate* viruses. Persistent infections typically involve the silencing of genes involved in lytic functions by a phage-encoded repressor protein. This cryptic state, termed *lysogeny*, can be maintained indefinitely. During cell division, the phage genome or *prophage* is regularly assorted to daughter cells either as an integrated part of the host chromosome (Ptashne, 1991) or as an extrachromosomal element (Bertani, 2004). In this fashion, the phage is maintained within the host population (Figure 24.2).

While lysogeny is highly stable, this relationship is not terminal. Environmental signals, particularly damage to host DNA, can initiate a cascade of cell responses that inactivate
FIGURE 24.2 Virus replication: temperate versus lytic. (1) All viral replication begins with virus attachment to host cell and the injection of viral nucleic acid into the host cytoplasm. (2) Viral nucleic acids (in white) are processed to allow replication. For many dsDNA viruses, this step involves circularization of a linear genome. Based on signals received from the host cell, the virus may proceed through one of two replication pathways. *Lytic replication*: (4) Early viral genes are expressed. The host chromosome is restricted (dashed black lines) and typically used as building blocks for the replication of new viral genomes (white circles). (7) Late viral genes are expressed: viral structural proteins are synthesized and self-assemble into multisubunit structures such as the procapsid, tail, and baseplate. (8) Viral genomes are packaged into capsids and component subunits (capsids and tails) self-assemble into mature virions. (9) Viral-mediated host cell lysis releases newly produced viruses into the environment. *Lysogenic replication*. (3) Viral repressor protein prevents the expression of early viral genes by blocking transcription. Viral DNA (white) is integrated into the host chromosome (black) through a recombination process mediated by both viral and host proteins. (5) Stable integration enables transmission of the viral genome (prophage) to subsequent generations of daughter cells, leading to a population of lysogens—host cells that carry prophage. (6) Induction. Damage to host DNA (indicated by lightning bolt) and other environmental stimuli may cease prophage repression and the virus shifts into lytic replication mode as early viral genes are expressed (4).

the phage repressor protein. Following this event, known as *induction*, the virus shifts into lytic replication and progeny virus particles are released into the environment through cell lysis. While little is known about the factors leading to the establishment of lysogeny in nature, it is generally believed that lysogeny provides a refuge for temperate phages when host abundance is low or conditions are poor for robust viral replication (i.e., cells are starved) (Stewart and Levin, 1984; Marsh and Wellington, 1994).

24.1.3 Impact of the Soil Environment on Virus Replication Mode

The spatial heterogeneity and temporal variability of soils can be extremely high and may select for the predominance of specific viral replication strategies. In particular, lysogenic replication appears to hold a distinct advantage for viruses in soils, as lysogeny supports the long-term maintenance of phages within host populations (Stewart and Levin, 1984; Pantastico-Caldas et al., 1992; Marsh and Wellington, 1994). Recent investigations into the frequency of inducible lysogeny among soil bacteria isolated on laboratory media (Williamson et al., 2008) and within natural assemblages of soil bacteria (Williamson et al., 2007) indicate that inducible lysogens (i.e., bacteria carrying a prophage element) account for approximately 30%, and in some cases over 60%, of the total bacterial population in a given soil. While this is a significant fraction and suggests that many soil phages are temperate, soils also contain appreciable numbers of lytic viruses, many of which have been isolated and characterized (described later). Thus, the importance of lytic viruses to the ecology of soils should not be underestimated.

24.1.4 Detection and Enumeration of Viruses in Soils

Well-characterized viral pathogens are frequently detected in soils using PCR assays, in which specific oligonucleotide primers are designed to amplify the viral DNA (or cDNA generated from viral RNA) from environmental samples. This approach has been used to detect specific plant (Farzadfar et al., 2007; Budge et al., 2008) and animal viruses (Chancellor et al., 2006) in soils. Soil viruses may be detected and enumerated through additional direct or indirect approaches. The most common indirect method for enumerating soil viruses is the plaque assay, which pertains primarily to bacteriophages.

24.1.4.1 Plaque Assay

In the plaque assay, a soil suspension is filtered to remove bacteria and other organisms. The filtrate is then diluted and mixed with an actively growing culture of a specific bacterial host strain and molten agar. The mixture is spread over solid agar media and the molten top agar is allowed to solidify. The plate is then incubated to allow for bacterial growth. If the filtrate contained any infectious phages, this will be apparent as *plaques* or zones of clearing in the bacterial lawn (Figure 24.3a). The number of plaques reflects the number of infectious virus particles present in the soil at the time of sampling. Similar infective assays are used to detect and enumerate animal or plant viruses except that tissue cultures, or in some cases, whole organisms, are used rather than bacteria grown on agar plates. A major shortcoming of infective assays is that detection and enumeration are limited only to specific viruses capable of propagating within the target organism(s), under the specific conditions tested (temperature, humidity, etc.). Thus, infective assays provide no information about total viral abundance in soils.

24.1.4.2 Viral Direct Counts

Total virus abundance in soils may be assessed through transmission electron microscopy (TEM) or epifluorescence microscopy (EFM), each of which enables the direct counting of virus particles. Both of these direct counting procedures require efficient dispersion of soil aggregates and extraction of virus particles from the soil matrix into an aqueous carrier phase. Physical dispersion has been accomplished through bead-beating (Ashelford et al., 2003), mechanical blending (Swanson et al., 2009), or sonication (Williamson et al., 2003, 2005, 2007) of soils suspended in buffer, such as 1% potassium citrate. The suspension is typically filtered to remove bacteria prior to further processing. For EFM enumeration, virus suspensions are passed though 0.02 μm pore filters and the captured virus particles are stained with a fluorochrome that binds to nucleic acids (Williamson et al., 2003).

(a)　　　　　　　　(b)　　　　　　　　(c)
FIGURE 24.3　Methods for detecting and enumerating soil viruses. (a) Plaque assay, the number of infectious virus particles is estimated from the number of infectious centers or plaques apparent on plates of host. (b) Epifluorescence microscopy, digital images of fluorescently labeled virus particles are captured using a CCD camera and typically counted using image analysis software. (c) Transmission electron microscopy, images of virus particles are captured digitally or on film, and counted manually.

Filters are viewed under an appropriate excitation wavelength for the fluorochrome stain and the emitted fluorescence signals from the stained virus genomes are captured digitally using a charge-coupled device (CCD) camera (Figure 24.3b). For TEM enumeration, additional purification such as density gradient centrifugation is necessary prior to loading samples onto EM grids, so as to clearly visualize virus particles. Grids are then stained with an electron-dense heavy metal salt, such as uranyl acetate or phosphotungstic acid, and virus particles are visualized in a transmission electron microscope (Figure 24.3c).

While TEM allows for visualization of viral morphology, electron microscopy entails higher operating costs, increased sample processing time, and poorer capture efficiency leading to lower abundance estimates. EFM is cheaper and allows high sample throughput with much higher capture efficiency but does not allow for visualization of fine structure. Furthermore, EFM may detect false-positive fluorescence signals from nonviral sources; thus, care must be taken in processing images to obtain viral direct count data.

The first TEM-based estimates of viral abundance in an agricultural soil from the United Kingdom placed soil viral abundance on the order $10^8 \, g^{-1}$ (Ashelford et al., 2003). Later EFM-based estimates found that viral abundance varied from $8 \times 10^8 \, g$ dry weight^{-1} (g dw^{-1}) in agricultural soils to $4 \times 10^9 \, g$ dw^{-1} in wetland soils of the temperate Mid-Atlantic region of the United States (Williamson et al., 2005). Attempts at direct counting of viruses in soils from hot deserts such as the Sahara and Namib indicate that extracellular virus particles are below the limits of detection in these ecosystems (Prigent et al., 2005; Prestel et al., 2008). However, soils from the cold desert ecosystem of the McMurdo Dry Valleys, Antarctica, were estimated to contain between 9×10^7 and 8×10^8 viruses g dw^{-1} (Williamson et al., 2007). These patterns of abundance broadly indicate the physical environmental variables that control viral abundance within a given soil ecotype.

24.1.5 Factors Controlling Viral Abundance and Persistence

In temperate soils, viral abundance is significantly correlated to bacterial abundance (Williamson et al., 2007). This supports the generalization that most viruses in these soils are phages and indicates that the presence and abundance of susceptible hosts are a key factor controlling viral abundance. When host organisms are present, particularly in high numbers, new viruses may be continually produced and released into the soil matrix through acute infections. In the absence of susceptible hosts, the abundance of extracellular viruses is controlled by physicochemical properties of the soil environment. Adsorption to soil surfaces, which is presumably the natural state of soil viruses, has been shown to enhance the persistence of infectious virus particles (Lipson and Stotzky, 1986). Thus, the number and types of colloidal surfaces affect total viral abundance in a given soil (Meschke and Sobsey, 2003; Zhuang and Jin, 2003a). Soils with higher clay and organic matter contents generally provide larger surface area for adsorption of viral particles and harbor higher viral abundances.

Soil moisture content is a key factor controlling viral abundance and persistence in soils, as thicker water films have smaller interfacial areas (air–water interface, solid–water interface, and triple-phase boundary), and surface tension created at interfaces tends to inactivate viruses (Gerba, 1984; Jin and Flury, 2002; Zhuang and Jin, 2003b; Torkzaban et al., 2006). The pH of the soil solution (Loveland et al., 1996) is another important abiotic factor controlling viral abundance, with higher abundances generally occurring in neutral pH soils. Lower pH generally favors stronger adsorption of viruses to soil surfaces (Gerba, 1984); thus, it is unclear whether higher viral abundances in neutral soils is due to reduced persistence of intact virions in acid soils or more efficient extraction of virions from neutral soils. Temperature significantly influences viral persistence and abundance in soils (Duboise et al., 1979; Wen et al., 2004). Generally, lower temperatures foster the persistence or preservation of viruses while higher temperatures promote thermal decay of viral particles.

24.1.6 The Virus-to-Bacterium Ratio

The ratio of viral abundance to bacterial abundance (virus-to-bacterium ratio, or VBR) has been used as a metric for determining relationships between viral production/decay and bacterial production/infection in aquatic ecosystems (Wommack and Colwell, 2000). Two significant trends have emerged regarding VBR in all aquatic ecosystems examined to date, despite large disparities in temperature, salinity, and trophic status of these ecosystems: (1) viral abundance is significantly correlated to bacterial abundance, and (2) the range of VBRs is surprisingly narrow, typically varying from 1 to 50 with a mean value of about 10 (Wommack and Colwell, 2000; Weinbauer, 2004). Significant correlations between viral and bacterial abundance suggest a close coupling between viral and bacterial production in aquatic environments, while the narrow range of VBRs may indicate balanced rates of viral production and decay.

In contrast to the relatively narrow range of VBRs in aquatic systems, including marine and freshwater sediments, VBRs of soils encompass a range of several orders of magnitude (Table 24.1). The low VBRs of wetland soils (Williamson et al., 2007) suggest that in perennially wet, temperate soils, viral and bacterial production are tightly linked and viral production and decay are closely balanced. The relatively higher VBRs of agricultural soils are due largely to the fact that bacterial abundances in agricultural soils were lower than those of wetland soils by 100-fold or more (Williamson et al., 2007). Regular tillage and disturbance of agricultural soils is known to negatively impact bacterial abundance (Feng et al., 2003; Helgason et al., 2009) and likely accounts for the decrease in bacterial abundance and concomitant increase in VBR. The higher VBRs of agricultural soils may also indicate a disconnect between viral production and decay, where viruses are produced faster than they are destroyed or removed from the system.

The remarkably high VBRs recorded for Antarctic soils (Williamson et al., 2007) are most likely due to long-term storage

TABLE 24.1 Comparison of Virus-to-Bacterium Ratios across Ecosystems

Ecosystem	Reference	Method	VBR
Aquatic (various)	Wommack and Colwell (2000)	EFM/TEM	0.5–50
Sediment (various)	Helton et al. (2006)	EFM/TEM	0.03–107
Soil (wetland)	Williamson et al. (2007)	EFM	10–60
Soil (agricultural)	Williamson et al. (2007)	EFM	330–470
Soil (Antarctic)	Williamson et al. (2007)	EFM	170–8100
Soil (Sahara)	Prigent et al. (2005)	TEM	$<10^{-3}$

TEM, transmission electron microscopic direct counts; EFM, epifluorescence microscopic direct counts.

of viruses. A multiplicity of growth-limiting conditions, including low temperature, lack of free water, and scarcity of organic substrates for growth, explains the low bacterial abundances in these soils. It is unlikely that the sparse bacterial population is capable of supporting such a burgeoning population of viruses. Since viruses are known to persist longer when adsorbed to surfaces (Lipson and Stotzky, 1986; Vettori et al., 1999) and kept at low temperatures (Duboise et al., 1979; Wen et al., 2004), it is likely that viral abundances obtained for Antarctic soils largely comprise stored viruses.

The very low VBRs for Saharan sands indicate that extracellular viruses are relatively rare in these environments. Indeed, the abundance of extracellular virus particles was below the limits of detection by TEM, whereas bacterial abundance in these sands was about $10^4\,g^{-1}$ (Prigent et al., 2005). Low bacterial abundance in Saharan sands is conflated with a low growth rate, neither of which could be expected to support a large viral population. While the low bacterial abundance and production rates are also characteristic of Antarctic soils, the environmental conditions leading to this situation in the Sahara are completely different and likely explain the conspicuous lack of extracellular viruses. Saharan sands experience large diurnal fluxes of temperature, severe doses of UV radiation, near-perpetual arid conditions, and aeolian abrasion, all of which likely contribute to the destruction of extracellular virus particles shortly after they are released.

While VBR may indicate linkages between host production, viral production, and viral decay in aquatic ecosystems, the value of VBR for soil ecosystems remains contentious, as critical questions surround what VBR is measuring. What fraction of extracted soil viruses are infectious or active at the time of sampling? What fraction of extracted bacteria is active? Do the extracted viruses have anything to do with the extracted bacteria, whatsoever? And how accurate are the estimates of both bacterial and viral abundance used to compute this ratio? In order to answer these questions and advance our understanding of soil viral ecology, additional experiments are needed, which explore (1) survival and/or decay rates for autochthonous soil viruses within various soil ecosystems, (2) site-specific factors leading to the destruction or removal of viruses from soil, and (3) improvements in the extraction of bacteria from soil and in estimations of bacterial extraction efficiency.

24.1.7 Viral Diversity

24.1.7.1 Morphological Approaches

The earliest characterization of soil viral assemblages relied upon TEM to render a morphological assessment of diversity (Williamson et al., 2005). The use of TEM approaches was necessary owing to the slow and problematic development of molecular genetic approaches to specifically assess viral diversity in soils, particularly when compared to the suite of methods then available to study viral assemblages in aquatic environments. Despite the low resolution of TEM-based estimates, the distribution of virus morphotypes observed in six different soils (including agricultural, forest, and wetland soils) indicated that the viral communities of each soil were distinct (Williamson et al., 2005). Interestingly, phages with elongated capsids were observed in five of the six soils. Phage particles with elongated capsids have also been observed in samples of Saharan sands (Prigent et al., 2005). Apart from these few observations, this morphotype has been rarely reported among environmental samples and comprises fewer than 2% of all known phages (Ackermann, 2001). Thus, assemblages of soil viruses present unique and novel features even at this level of resolution. The predominance of tailed viral morphotypes indicated that bacteriophages were the most abundant viral type within all six soil environments. The mean capsid diameter for soil viruses was about 50 nm, with a range of 20–160 nm (Williamson et al., 2005).

24.1.7.2 Molecular Approaches

24.1.7.2.1 Marker Genes

Viruses possess no single, universally conserved phylogenetic marker analogous to the prokaryotic 16S rRNA gene; this has hampered efforts to obtain a comprehensive view of viral diversity and phylogeny. Nevertheless, investigators have used certain marker genes thought to be highly conserved among specific viral families to assess phylogenetic relationships within these families. For example, PCR assays have shown that gene homologues of T7-like DNA polymerase can be commonly found in a broad range of environments, including soils (Breitbart et al., 2006). However, many commonly used phage marker genes (e.g., g23, g20, and T7-like DNA polymerase) may not be routinely found in all soils (Srinivasiah et al., 2008). This limits the applicability of the present array of marker gene PCR assays for examining viral diversity across soils. By and large, most marker gene surveys of viral genetic diversity have been developed for use in aquatic environments. Thus, gene targets that are more specific to autochthonous soil viruses are needed to fully realize the potential of marker gene approaches for assessment of viral diversity in soils.

24.1.7.2.2 Randomly Amplified Polymorphic DNA-PCR

Randomly amplified polymorphic DNA-PCR (RAPD-PCR) relies upon a single primer (typically 10 nucleotides long) to amplify DNA fragments from a heterogeneous mixture of DNA templates. Subsequent separation of RAPD-PCR amplicons by gel electrophoresis generates banding patterns indicative of the underlying

complexity of the original DNA template mixture. In the case of viral assemblages, the template mixture is viral genomic DNA, and the complexity of the RAPD fingerprint serves as a proxy indication of viral genotype richness within a given sample. The approach is termed "random" as the choice of specific primers need not be based on actual sequence information from the target DNA.

RAPD-PCR has been used to assess the richness of virioplankton assemblages in the marine water column (Winget and Wommack, 2008), marine sediments (Helton and Wommack, 2009), and recent experiments indicate the potential utility of this approach in soils (Srinivasiah et al., 2008). However, further methodological refinements are needed before RAPD-PCR can be routinely applied to surveying the composition and diversity of soil viral assemblages.

24.1.7.2.3 Metagenomics

Metagenomics refers to the sequencing of the collective genomic DNA from a microbial assemblage within a specific environmental sample. Metagenomic analysis is a particularly powerful—and increasingly popular—tool for studying the genetic diversity of viral assemblages within environmental samples because sequence data can be obtained for (theoretically) the entire viral assemblage without dependence upon cultivation techniques, marker genes, or prior sequence knowledge. This approach comprises several steps, beginning with the extraction of virus particles from the sample matrix.

24.1.7.2.3.1 Construction of a Viral Metagenome Library The linker-amplified shotgun library, or LASL, has become the *de facto* standard for cloning and sequencing the typically small amounts of viral DNA obtained from environmental samples (Wommack et al., 2009). Once extracted from the soil, viral capsids are denatured and the released DNA is isolated, purified, and sheared into small fragments of one to a few tens of kilobases in size. Shearing is important as it reduces the probability of cloning complete virus genes whose products would be lethal to the cloning system (e.g., holins, lysins). The fragments of viral DNA are end-repaired and ligated to short double-stranded oligonucleotides called linkers. The linker-adapted viral DNA fragments can then be amplified in a PCR reaction, using the linker sequences as priming sites. Amplification *in vitro* not only increases the amount of fragmented viral DNA available for downstream cloning reactions but also removes modified bases, increasing the success of cloning reactions. After size selection of DNA fragments, typically by gel electrophoresis, the linker-amplified viral DNA fragments are cloned into a specific vector, which is then transformed into *Escherichia coli* hosts via electroporation. Cloning vectors used for viral metagenome projects (e.g., pSMART) typically employ transcription terminators flanking the insertion site as an additional protection against the expression of lethal gene products encoded by the viral insert.

Recent technological improvements in the throughput and cost of DNA sequencing have eliminated the necessity of a fragment cloning step (Margulies et al., 2005). Initially, these approaches typically produced shorter sequence read lengths, which perform poorly in subsequent bioinformatic analyses as compared to more established DNA sequencing technology that requires cloning (Wommack et al., 2008). However, manufacturers of second generation sequencing technology are continually striving to increase sequence read length; thus, it is likely that soon, cloning-independent approaches will become the standard for metagenome analyses.

24.1.7.2.3.2 Analysis of Sequence Data in Viral Metagenomes Once a large collection of insert nucleotide sequences within the plasmid clone library has been obtained, individual fragments are assembled into contiguous stretches (*contigs*) with a computer algorithm, according to user-defined match and sequence overlap parameters. Assembly results can then be described by a metric known as the *contig spectrum* (Angly et al., 2005), which indicates the number of assembled contigs containing one sequence (i.e., singletons), two sequences, three, four, and so on. The experimental contig spectrum is used to test predictions about the rank-abundance distribution of viral genotypes within the original environmental sample. In most cases, the power-law rank abundance distribution has produced the smallest error for experimental contig spectra of viral metagenomes (Angly et al., 2005; Fierer et al., 2007). Open reading frames (i.e., putative genes) are typically identified within the contigs using software packages that recognize specific features within the DNA sequence, such as start and stop codons, and ribosome binding sites (Noguchi et al., 2006). This step is usually followed by manual verification and deeper searches to determine the possible taxonomic origin and putative function based on the identity of the closest known homologue.

In the first published metagenomic analysis of soil viral assemblages, the bacterial, fungal, and viral communities of three soils were compared, representing tallgrass prairie, desert, and tropical rainforest ecotypes (Fierer et al., 2007). According to contig spectra analysis, assemblages of soil viruses were found to be extremely rich both on a local and global scale, with up to 10^8 estimated viral genotypes in one soil and only one overlapping sequence in a total of 4577 sequences. These findings suggest that each soil viral assemblage is a distinct microcosm of unique sequences, sharing little in common with viral assemblages from other soils. This contrasts with metagenomic characterizations of marine virus assemblages, which found between 85% and 95% of the most abundant virus genomes were shared among four discrete sampling locations (Sargasso Sea, the Gulf of Mexico, coastal waters of British Columbia, and the Arctic Ocean) (Angly et al., 2006). While marine viral assemblages may be locally diverse but share much in common on a global scale, the available data regarding soil viral assemblages indicates that soil viruses are much more diverse than their marine counterparts. This is consistent with initial results from RAPD-PCR-based assessments of viral genotype richness in soils (Srinivasiah et al., 2008). In all, a number of different techniques are currently available to assess viral diversity in soils. Each technique encompasses innate strengths and weaknesses in terms of cost, ease of analysis, and limits of resolution (Table 24.2).

TABLE 24.2   Comparison of Available Techniques for Assessing Viral Diversity in Soils

Technique	Morphology	Marker Genes
Strengths	1. Abundance data can be obtained simultaneously	1. Low cost, high throughput
	2. Allows for observation of rare or novel morphotypes	2. Allows rapid screening of many samples
	3. Morphology data may be obtained for (theoretically) all viruses in a given sample	3. Can be combined with sequencing to obtain additional information on genetic diversity
	4. Procedures and analysis can be performed by an individual researcher	4. Procedures and analysis can be performed by an individual researcher
		5. Provides information on hosts and their functional diversity in soils
Weaknesses	1. Low throughput, laborious	1. Data may only be obtained for specific viral groups
	2. Low resolution (ICTV family), allows for comparative analyses	2. Relatively low resolution (presence/absence), allows for comparative analyses
	3. Cost may be an issue	3. Development of primers requires prior sequence knowledge
Technique	RAPD-PCR	Metagenomic Libraries
Strengths	1. Low cost, high throughput	1. Extremely high throughput
	2. No prior sequence knowledge required	2. Extremely high resolution (nucleotide level), allows for robust estimates of genotype richness, evenness, as well as comparative analyses
	3. Moderate resolution (banding pattern), can also be combined with sequencing for additional information on genetic diversity	3. Data may be obtained for (theoretically) all dsDNA viruses in a given sample
	4. Procedures and analysis can be performed by an individual researcher	4. Requires no prior sequence knowledge
Weaknesses	1. Data may not be obtained for all viral groups	1. High cost
	2. Allows for comparative analyses	2. Annotation not necessarily high throughput
	3. Development of primers may require extensive trial and error	3. Procedures and analysis typically require a team of researchers
		4. Coverage depends on sampling efficiency and depth of sequencing
		5. Lack of viral taxonomic information to classify unknown sequences

24.1.8 Impacts of Virus Activity in Soils

24.1.8.1 Bacterial Mortality, Clonal Diversity, and Community Succession

As with viruses in marine ecosystems, viruses in soils play important roles in mediating bacterial mortality and controlling the clonal diversity of bacterial assemblages. Until recently, these impacts have only been demonstrated using specific phage-host systems. For example, rhizobia-specific phages (rhizobiophages) can exert selective pressures on the population of soil rhizobia, a broad class of nitrogen-fixing bacteria that engage in symbiotic relationships with leguminous plants. Infection and lysis of sensitive rhizobia strains results in a prevalence of phage-resistant mutant rhizobia that tend to be poor at colonizing plant roots (Kleczkowska, 1971). Apparently, the loss of phage receptor that results in resistance to infection also negatively impacts the microbe–plant interactions that are critical to productive symbioses. In addition, the presence or absence of specific rhizobiophages within a soil ecosystem can dictate which of many competing rhizobia strains are available for successful nodulation (Hashem and Angle, 1990). Beyond the impacts on bacterial mortality and selection, the lytic activity of rhizobiophages influences the efficacy of the legume–rhizobia symbiosis and may contribute to rates of nitrogen fixation and overall soil fertility.

Field experiments focusing on the population dynamics of specific, cultivable bacteriophages in the sugar beet rhizosphere revealed that phage and host dynamics exhibit recurring annual cycles, with temporal dynamics of phage and host populations appearing almost identical over three consecutive years (Ashelford et al., 1999a, 1999b). Thus, soil viruses appear to play important roles in the succession of microbial communities within soils.

Recent microcosm experiments indicate that soil bacterial communities and associated viral assemblages are highly dynamic and responsive to perturbations. The addition of various carbon amendments to soil within microcosm incubations resulted in significant fluctuations in bacterial abundance. Furthermore, a distinct coupling effect was observed, wherein an increase or decrease in bacterial abundance co-occurred with a respective decrease or increase in viral abundance, albeit with a time lag between virus and host fluxes (Srinivasiah et al., 2008). These patterns of staggered fluctuations between soil viruses and soil bacteria closely follow conventional models of predator–prey dynamics. Thus, results from microcosm experiments suggest that viral-mediated mortality is a significant factor controlling bacterial abundance, and by association, biomass turnover, and rates of nutrient cycling in soil ecosystems.

24.1.8.2 Phage Conversion, Host Fitness, and Horizontal Gene Transfer

Temperate phages are known to affect host fitness through a process known as *lysogenic conversion*. Prophage elements may contain genes that are beneficial to host survival and proliferation under specific conditions, thus providing a selective advantage over nonlysogenized hosts (Barksdale and Arden, 1974; Barondess and Beckwith, 1995; Waldor and Mekalanos, 1996).

Prophages also frequently constitute the sole differences in specific gene complement among closely related strains of bacteria and, consequently, the range of relationships between the lysogenic host bacterium and other organisms (Ohnishi et al., 2001; Desiere et al., 2002; Nakagawa et al., 2003; van der Mee-Marquet et al., 2006). Most of the data supporting these observations come from clinical strains of bacteria, and very little data are available regarding these same phage impacts on environmentally relevant strains. However, recent investigations indicate that lysogeny is highly prevalent among autochthonous communities of soil bacteria, with inducible lysogens (i.e., bacteria carrying a prophage element) accounting for 4%–66% of the total population in a given soil (Williamson et al., 2007). Thus, if the impacts of temperate phages observed in clinical settings hold true for environmental bacteria, the high frequency of lysogeny among soil bacteria implies that temperate viruses in soils significantly influence host fitness and evolution through the genetic process of lysogenic conversion.

Viruses may have significant impacts on host population genetics by acting as vectors for the horizontal transfer of genes between dissimilar bacterial strains. Bacteria may horizontally acquire novel gene sets via three mechanisms: (1) transformation, the uptake of naked DNA from the environment by competent cells; (2) conjugation, the transfer of genetic material from one cell to another through a pilus; and (3) transduction, phage-mediated transfer of DNA. Transduction begins as an error during the phage replication process in which host genomic DNA is mistakenly packaged into virus capsids. Two types of transduction are possible, generalized or specialized, depending on the phenotype of the phage mediating the transfer.

Generalized transducing phages, which may be virulent or temperate, carry any gene from the host genome with nearly equal frequency regardless of its location on the chromosome. In contrast, specialized transduction is mediated only by temperate phages that integrate into the host chromosome. Only specific bacterial genes flanking the prophage insertion site are transferred due to improper excision of the phage genome from the host chromosome (Levy and Miller, 1989; Campbell, 2006). While transduction is a rare event leading to a low frequency of gene transfer, the short generation times and fast growth rates of bacteria means that even rare recombinations may quickly alter the genotypic diversity of a bacterial community (Beumer and Robinson, 2005).

In aquatic studies, the presence of particulate matter increased transduction frequencies by providing surface area on which phages and host cells could aggregate and interact (Ripp and Miller, 1995). Soil, especially the clay and organic matter fractions, has an extremely high specific surface area ($80-800 \, m^2 \, g^{-1}$; Hillel, 1998), providing many potential sites for phage and host adsorption and interaction. However, natural transduction has never been observed in soil environments. Furthermore, only a handful of experiments using cultivable phage-host systems have been performed, all of which underscore the potential for transduction in soils (Vettori et al., 1999, 2000; Deb et al., 2003). A more recent study of the importance of phage-mediated gene transfer in soils examined viral assemblages that were obtained from the induction of soil bacteria in atrazine-treated soils. Subsequent PCR screening detected the presence of the atrazine catabolic gene *trzN* within the induced phage community, indicating that this important phenotypic trait could be transferred among bacterial populations through phage vectors (Ghosh et al., 2008). While much uncertainty remains regarding the frequency of transduction in soil environments, the possible impacts on bacterial genetic diversity and evolution are immense.

24.2 Structure and Function of Prokaryotes in Soil

Michael Schloter

24.2.1 Introduction

Prokaryotes can be regarded, based on pure numbers, as the most important group of organisms in soils. It has been estimated that 1 g of soil harbors up to 10 billion microorganisms, belonging to up to 100,000 different species (Amann et al., 1995). Craig Venter compared the amount of genetic information stored in 1 g of soil to that of 4000 human genomes. But not only the numbers and the diversity of microbes are impressive, the amount of stored carbon and nitrogen in the microbial biomass exceeds the mass, which is stored in the plant biomass (Whitman et al., 1998). Prokaryotes are generally regarded as the catalysts for the major turnover processes in soil. Some metabolic steps, such as the fixation of atmospheric nitrogen and the biosynthesis of methane, are exclusively performed by bacteria and archaea. Furthermore prokaryotes are capable of efficiently degrading many pollutants. Finally, microbial communities highly influence plant growth positively as so-called plant growth–promoting rhizobacteria or negatively as phytopathogens. Most prokaryotes can adapt to extreme conditions, such as high salinity, drought or water stress, which is necessary to survive the changing conditions in soils. Therefore, the structure and activity of prokaryotic communities serves as important parameters for soil quality and one of the major goals of agricultural management is the steering of soil microbial communities ever since, to improve sustainable crop yield and quality.

Compared to eukaryotes, prokaryotes are characterized by a relatively simple structural level. They are unlike most eukaryotes in many cases unicellular and have no nucleus. Often they are much smaller than eukaryotes. Most prokaryotes are between 1 and 10 μm. Generation time of prokaryotes is often much faster compared to eukaryotes. Furthermore, prokaryotes never harbor organelles like mitochondria or chloroplasts. However, prokaryotes do possess some internal structures, such as cytoskeletons. The genome of prokaryotes is characterized by a DNA–protein complex in the cytosol called the nucleoid, which lacks a nuclear envelope. Often prokaryotes contain small ring-like DNA fragments, called plasmids, which are easily transferable between organisms. These plasmids encode, for example, for resistance genes, which make prokaryotes tolerant against antibiotics or heavy metals. Prokaryotes reproduce through asexual reproduction. While prokaryotes are still commonly imagined to be strictly unicellular, most are capable of forming so-called biofilms. Both eukaryotes and prokaryotes contain large RNA/protein structures called ribosomes, which are involved in protein expression. Among the prokaryotes, two phylogenetically distinct domains could be distinguished: bacteria and archaea. It is generally accepted that the

TABLE 24.3 Some Important Differences between Prokaryotes and Eukaryotes

	Prokaryotes (Eubacteria and Archaea), pro = "before" and karyon = "nucleus"	Eukaryotes
Size of individual cells	1–10 μm	10 μm to 1 mm
Cell wall	Peptidoglycan (eubacteria)	Cellulose and chitin (plants and fungi)
Cellular organization	Mostly single cells	Mostly differentiation in several cell types
Organelles	No	Yes (mitochondria, ER, chloroplasts, etc.)
Location of genome	Naked ring-like DNA	Nucleus
Genome structure	One chromosome and plasmids	Several chromosomes (exon–intron structure)
Metabolism	Aerobic and anaerobic	Aerobic and anaerobic
RNA and proteins	Synthesis in same compartment	RNA synthesis in nucleus; protein synthesis in cytoplasm
Size of ribosomes	70S (30S + 50S)	80S (40S + 60S)
Reproduction	Binary fission	Meiosis (sexual reproduction) mitosis (cell division)
Evolution		More advanced having arisen from prokaryote-like predecessors

first living organisms were prokaryotes, approximately 3.5 billion years ago. Even today, prokaryotes are perhaps the most successful and abundant form of life. Details about prokaryotes can be found in reviews by Woese (1994) and Ogunseitan (2005). Some differences between Eukaryotes and Prokaryotes are given in Table 24.3.

However, for a long period, no tools were available to characterize microbes from soil, and even today, we still have huge difficulties in describing microbial diversity in this habitat.

24.2.2 The Methodological Challenge

Almost 30 years ago Vigdis Torsvik (Torsvik, 1980) published an article in *Soil Biology and Biochemistry* describing for the first time the isolation of bacterial DNA from soil. This paper is regarded as the initialization of molecular microbial ecology in soil.

Up to that date, most papers that had been dealing with microbial diversity and the corresponding physiological properties were based on isolation and traditional cultivation-based approaches, as it had been assumed that most microbes from soil can be easily isolated. And indeed this approach was useful in a way to get several thousand isolates in hand and to describe them. However, studies from the last decades have proven that this number of organisms is just the tip of the iceberg and true diversity in soil might be than 1000 above that, what is known

from cultivation-based approaches (Amann et al., 1995). Direct, simple staining of microorganisms in different natural compartments have indicated that the actual number of cells that can be found in different environmental samples exceed diversity based on plate counting by 2–4 orders of magnitude (Amann et al., 1995). These data gave a first indication that in general, less than 1% of the microflora from a soil sample can be assessed with simple cultivation methods. Unfortunately, some authors have greatly simplified these findings and concluded that generally only 1% of all species can be isolated. This statement could be disproven simply by improving cultivation techniques, especially by adapting the media and the cultivation conditions to the appropriate environmental conditions. For example, Bruns et al. (2002) could show that the addition of cyclic AMP and homoserine lactones to traditional media, improves the cultivation efficiency of heterotrophic bacteria from the Black Sea. There are several hypotheses that explain reasons why microbes from the environment are difficult to be cultivated.

1. The so-called noncultivable cells are genetically closely related to culturable representatives, but their physiological status in the environment makes their isolation difficult or impossible. This interpretation seems plausible, because it is well known from pure culture studies, that under certain conditions, for example, starvation, microbes can turn into a status that is described as "alive but not culturable" (Binnerup et al., 1993). If this hypothesis is the only valid one, this would mean that up to 99% of the yet noncultured microbes are closely related to the 1% of microbes that have been isolated so far and just differ in their physiological status from the well-characterized isolates. However, molecular data indicate that diversity in soil is far increased to what we know so far from the cultured isolates.

2. Therefore, there is general agreement among scientists that there must be an additional reason why microbes from soil cannot be cultured easily. The second hypothesis, which might explain the difficulties in cultivation of the majority of microorganisms from environmental samples, assumes that many of these microorganisms belong to completely new lineages, which are phylogenetically not related to isolated microbes, which makes their isolation on standard media impossible. If this hypothesis is true, there must be still tens of thousands of new species in the nature, which until now were not isolated. A good indication on the proportion of isolated to yet undiscovered microbes is based on a comparison of sequences from marker genes (e.g., 16S rRNA genes) from isolates and PCR products of the corresponding gene from directly extracted DNA from soil (Pace, 1997). It is therefore not surprising that even today the majority of research in the field of "molecular microbial ecology," is based on the question how to identify new species from environmental samples and how to link their dynamics and activity to ecosystem functioning.

3. A third hypothesis derives from the fact that the nutrient supply in soils usually is very limited and extremely complex. Typical soil bacteria belong mostly to the so-called k-strategists, with relatively long generation times and high substrate affinity for complex substrates. Common culture conditions, however, are more likely to "r-strategists" with fast generation times and nutrients with a low complexity adjusted. Even taking generation times of only a few hours into account for typical soil bacteria would result in incubation times of several years to acquire a visible colony on an agar plate (Bakken, 1997; Vieira and Nahas, 2005).

The first step toward a broader assessment of soil microbes from soil was done in the eighties of the last century when PCR was introduced into soil microbiology and nucleic acids (mainly DNA) from soil samples was directly extracted and amplified to build a catalog of information, with the aim to clarify the question, "What is where?" In the pioneering work by Torsvik et al. (1990), the diversity of microbial communities in nature was studied with the help of DNA–DNA reassociation kinetics. The results indicated that DNA, directly extracted from the soil by fractional centrifugation, is much more complex than what had been expected at that time and that 1 g of soil harbors up to 10,000 different genomes (Torsvik et al., 1990). This study provided the basis for all investigations in microbial ecology.

The genes of the rRNA have been used as a marker for genetic diversity in the environment in the last two decades. The rRNA is composed of several conserved areas. Besides strongly conserved areas, which are similar in almost all organisms, the rRNA genes also contain variable and hypervariable areas, which allow a distinction up to the species level. The different conserved areas of the rRNA can be used also as "molecular clock" meaning that differences between two organisms in the rRNA gene sequences directly correlate with their phylogeny (Gupta, 2000, 2004; Rappe and Giovannoni, 2003). The highly conserved flanking areas on the other hand are ideal target regions for primers and can be used for an amplification of the corresponding variable regions by PCR. Until today, in public accessible databases approximately 65,000 rRNA sequences have been deposited (www.ncbi.nlm.nih.gov). This enormous amount of data allows a very precise phylogenetic assignment of unknown sequences from environmental DNA. Therefore, rRNA genes are often called the "gold standard" in microbial ecology. The characterization of the obtained PCR fragments can be done by different fingerprinting methods. This includes denaturing gradient gel electrophoresis (DGGE), the analysis of single-strand conformation polymorphism (SSCP), or restriction length polymorphism (RFLP) (Liu et al., 1997; Muyzer et al., 1998; Dohrmann and Tebbe, 2004). This technique will be described in this book by Kornelia Smalla. However, since the introduction of capillary sequencing technology in microbial ecology amplicons are often directly cloned and sequenced. This approach offers the advantage that the sequences can be directly analyzed with the help of appropriate software programs (e.g., ARB, Ludwig et al., 2004)

and used as the basis for the development of fluorescence in situ hybridization (FISH), which can be used for the in situ detection of the corresponding phylotypes in soil (full rRNA cycle approach, Amann et al., 1995).

Interestingly, even today, almost 30 years after the first extraction of nucleic acids from soil has been described, no standard protocol is available. There are only some very general criteria for nucleic acids extracted from soils available, if they should be amplified by PCR (Thakuria et al., 2008). This include the ratio OD 260/230 nm respectively 260/280 nm, which give information about the quality of nucleic acids extracted and the amount of humic substances coextracted, which might inhibit PCR reaction. Interestingly, in the paper stated above, it could be shown that not only the quantity and quality of DNA extracted from soil is depending on the protocol used but also the obtained diversity pattern, as different methods show different extraction efficiencies of nucleic acids for selected microbial groups from soil. This can result in changes in diversity patterns from the same soil, depending on the methods used for extraction of nucleic acids (Bakken and Frostegard, 2006).

However, also molecular, PCR-based methods only allow the detection of a part of the overall microbial diversity in soil. This fact is mainly related to general features of the PCR reaction, as mainly the amplicons generated in the first cycles of PCR determine the final composition of PCR products at the end after 30 or 35 cycles. This so-called preferential amplification of certain target sequences is a well-described phenomena and becomes more important if so-called universal primer sets are used to describe the whole bacterial or archaeal community (Becker et al., 2000). If more targeted primer sets are used to describe the diversity of certain phylogenetic groups, this bias becomes less importance. Furthermore, the generation of microbial fingerprints based on the rRNA gene does only allow a description of communities based on the species level. Ecotypes and strains cannot be distinguished by this approach. Therefore, individual ecotypes or strains must be characterized by other methods (Schloter et al., 2000).

Therefore, it is often suggested to use a combination of methods to describe microbial communities in soil that are not only based on the genotype of microbial communities but also in their phenotype (e.g., analysis of phospholipid acid pattern from the outer membrane or cell wall of microbes, PLFA; Zelles, 1997). These approaches are complementary to the molecular analysis, though mainly detection on the level up to the domains and large groups is possible and given environmental conditions can influence the results. However, PLFA analysis compared to PCR-based methods is less biased, since the extracts are analyzed by GC/MS directly. For detailed studies on the level of ecotypes up to now, only cultivation-dependent methods have been described (Schloter et al., 2000), including all problems mentioned above.

It was therefore suggested by Tebbe and Schloter (2006) that various methodological approaches should be combined to describe microbial communities in soil. The corresponding "polyphasic approach" is shown in Figure 24.4. Such a concept may help to overcome possible methodological limitations that

Consequences for the ecosystem

Sensitivity of the method

Microbial biomass
(z.B. Substrate induced respiration) (1)

Domains and families
(PLFA pattern) (2)

Species
(PCR-based methods) (3)

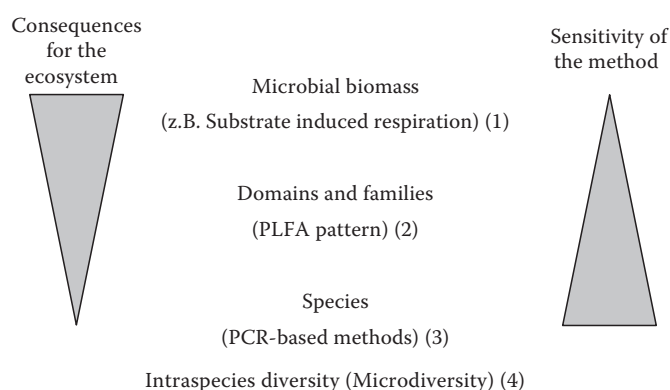
Intraspecies diversity (Microdiversity) (4)


FIGURE 24.4 Hierarchic–polyphasic approach to characterize microbial diversity in soils (1) Anderson et al. (1978); (2) Zelles (1997); (3) Amann et al. (1995); and (4) Schloter et al. (2000).

can occur when only one technique is applied on the one hand and to describe diversity of microbes at different taxonomic and phylogenetic levels.

In future, however, we might see a second revolution in microbial ecology, as more and more "high throughput sequencing" approaches become popular and are also used in microbial ecology. These new methods allow a genetic assessment of whole "metagenomes" from soil without generation of PCR products in very short time periods and to very cheap prices. However, there are still huge problems on how to handle and evaluate the generated sequence data (Urich et al., 2008).

24.2.3 Parameters Controlling the Composition of Prokaryotic Communities in Soils

Plants are highly influencing the composition of bacteria and archaea in the rhizosphere. These interactions between plants and prokaryotes are manifold and complex. They range from general nutrient mobilization and implementation to production of specific signaling molecules that allow a specific interaction. These interactions form the basis for both a natural nutrient management of plants as well as for healthy vegetation. However, it should not been overseen that also bulk soil microflora influences composition of bacteria and fungi in the rhizosphere (De Ridder-Duine et al., 2005).

The interactions between plants and prokaryotes are mainly driven by the carbon flow in the rhizosphere. The compartment of soil, that is directly influenced by the root, has been defined as rhizosphere. The rhizosphere is characterized by a high microbial biomass and activity and is considered as the most active soil habitat. The plants drive, by the excretion of exudates and nutrients, the composition of bacteria and archaea in the rhizosphere. The main components of carbon within the rhizosphere are organic acids, amino acids, and sugars in the rhizosphere of young roots and high-polymeric substances in the rhizosphere of older roots (Killham and Yeomans, 2001). In addition, certain signaling molecules such as furanones formed by the plant and bacterial *N*-acyl homoserine lactones induce

a strong cross talk between biota in the rhizosphere (Teplitski et al., 2000). Recent papers have shown additionally the importance of plant derived phenols, for the regulation of microbial activities in the rhizosphere (Bais et al., 2006). The mean turnover rates of organic compounds are approximately 2.5 years in rhizosphere soils. In contrast, in habitats with a relatively inactive microflora, such as the B horizon of an arable soil, turnover rates from 1000 to 2000 years for organic compounds have been calculated (Whitman et al., 1998).

Conversely, plants benefit largely from most of the chemical transformation products catalyzed by bacteria and archaea. The interaction between plant and prokaryotes can be even closer and symbiosis-like structures can be formed. The best known symbiosis is that involving rhizobia and legumes (Werner, 1992). In some cases, also other highly specific interactions between different microorganisms and some plant species have been described (Kowalchuk et al., 2002; Wardle, 2005). A typical example is the production of antibiotics by biocontrol-active microorganisms in the rhizosphere, resulting in a decreased risk of infection for the plant by phytopathogenic bacteria or fungi (Raaijmakers et al., 1997).

In addition to the rhizosphere, plants highly influence microbial community structure and function also in the litter layer, as the quality and quantity of the leaves that reach the ground drives the composition of the degrader community and consequently the kinetics of nutrient mobilization (Aneja et al., 2006).

Besides the interactions with plants, prokaryotes form interactions with most other biota in the soil like fungi, protozoa, nematodes, earthworms, and insects (Czarnetzki and Tebbe, 2003). Especially for organisms that belong to higher trophic levels, bacteria and archaea play an important role in the gastrointestinal tract for the degradation of complex organic material.

Of course, also other factors such as soil type, rainfall conditions, temperature profiles, etc. play an important role for the formation and dynamics of microbial communities in soil.

In agricultural used soils, in addition to factors mentioned above, the type of agricultural management plays an important role for microbes. Mainly, the quality and quantity of fertilizers and pesticides used and the types of tillage and the cropping sequence influence the composition of prokaryotic as well as eukaryotic populations in soil. The individual variables are summarized in Figure 24.5.

24.2.4 Structure of Prokaryotic Communities in Soil

Both cultivation-dependent and cultivation-independent methods support the hypothesis that soils are one of the ecosystems with the highest microbial diversity on earth. Even soils, where a reduced diversity is expected, like in contaminated areas, diversity indices calculated were far above the expected (Perez de Mora et al., 2006). Investigations based on clone libraries of 16S rRNA gene amplicons have also shown that it is practically impossible to get identical sequence from the same soil even if more than 1000 clones are investigated (Podar et al., 2007).

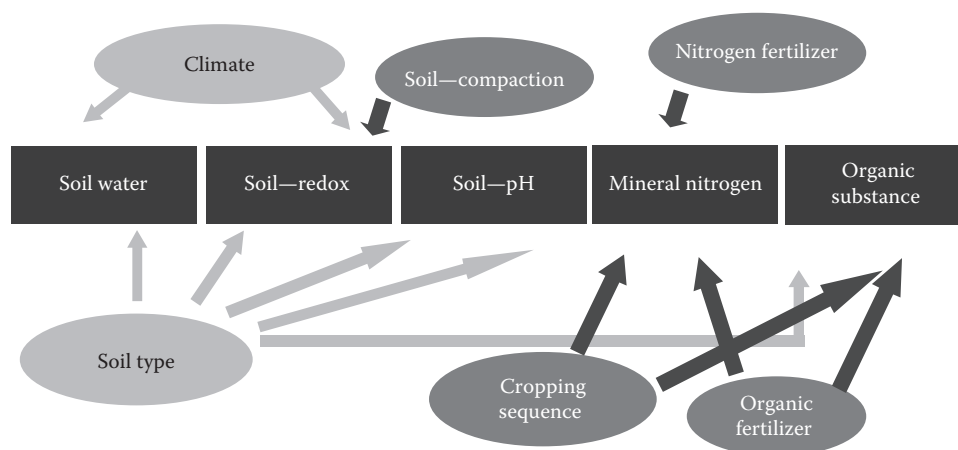
Most of the previously identified sequences belong to the group of Proteobacteria (Zavarzin et al., 1991; Gupta, 2000), Cytophagales (Dungan et al., 2003), Actinobacteria (Holmes et al., 2000; Ritz et al., 2004), or to the Gram-positive bacteria with low GC content (Felske et al., 1998). In the last two decades, quite often sequences from the Holophaga-Acidobacterium have been described from different soil samples (Ludwig et al., 1997; Barns et al., 1999; Felske et al., 1999) detected. Also, members of the group of Verrucomicrobia seem to be important members of soil microbial communities (Barns et al., 1999). Interestingly, there is increasing evidence that also sequences from organisms, which have been considered so far as less important from soil, such as planctomycetes (Wang et al., 2002) and spirochetes (Varm et al., 1994) can be easily detected in soil. Even the presence of high numbers of archaea in soils has been well described


FIGURE 24.5   Factors influencing microbial community structure and function in arable soils (light color: site; dark color: management).

based on typical biomarkers as well as on the basis of molecular methods (Leininger et al., 2006).

In comparison to the data published for the domains Bacteria and Archaea, results on the basis of 18S rRNA or its sequences for the description of fungal communities are rare; thus, a generalization, as described above for fungal communities is hardly possible at the moment based on the existing data.

24.2.5 From Structure to Function of Prokaryotic Communities in Soils

The structure of microbial communities does not necessarily help to clarify their function. Exceptions are simple ecosystems with relatively few species, such as microbial biofilms in hot springs. Therefore, studies on structure–function relationships were initially limited to those ecosystems. However, if processes and nutrient fluxes in complex biogeosystems should be better understood, information about microbial enzymes that are related to a particular turnover process and their expression in soils are of essential importance, as most of the ecologically relevant functions are distributed among different taxonomic groups of microbes in soil. For example, bacteria from the phyla Actinobacteria, Proteobacteria, Firmicutes, and Bacteroidetes are able to reduce cellulose (Ulrich and Wirth, 1999). The same is true for bacteria that are able to reduce nitrate or to fix atmospheric nitrogen (Zehr et al., 2003). The extent to which these functional redundancies contribute to the stability of soils is still unclear. However, it is clear that the development of such genetic diversity pattern in soils is strongly influenced by the microhabitat structure of soils (Gattinger et al., 2002; Webster et al., 2002; Franklin and Mills, 2003; Ritz et al., 2004).

To assess the potential of a soil for a specific turnover process, the amount and diversity of genes catalyzing the corresponding reaction serves as a good indicator. However, the analysis by PCR-based methods is often difficult, as appropriate primer systems are missing and often functionally identical genes in different organisms have low homology levels. One reason for this high divergence might be related to the fact that organisms, which share the same function, have developed independently during evolution, and, therefore, the coding sequences in particular at the nucleic acid level are strongly divergent. For example, exoproteases have a history of over 3.5 billion years (Mrkonjic et al., 2008). Therefore, not surprisingly in bacteria three classes of proteases have developed, which share the same function but are completely different in their structure and genetic composition (neutral-, metallo- and serine-proteases). If the entire bacterial community of a soil covering proteolytic activities should be measured for each of these enzyme classes, specific primers have to be developed. Other functional genes are significantly higher conserved, which indicates not coevolution but horizontal gene transfer. For example, the genes responsible for resistance against certain antibiotics are highly conserved in most bacteria mainly on the amino acid level

(Heuer and Smalla, 2007). Similarly, most of the genes coding for enzymes for the degradation of xenobiotics show high similarity. Many of these genes are localized on mobile genetic elements (Springael and Top, 2004). Overall, a transfer of complete gene sequences in soil between microorganisms is not a rare event (Clerc and Simonet, 1998). Especially in nutrient-rich microhabitats (such as the rhizosphere) and under the appropriate selection pressure, a transfer of genetic information can easily been demonstrated (Hoffmann et al., 1998; Smit et al., 1998; Thimm et al., 2001).

The alignments for the development of primer systems for the detection of functional genes can be done using existing sequences from databases in silico. However, the number of sequences available for functional genes is often very low and cannot be compared to the number of sequences present in databases for ribosomal genes, especially for the 16S rRNA coding gene. With a modification of the PCR, besides a qualitative assessment of diversity, also the quantification of genes of interest is possible (real time PCR; Sharma et al., 2007b).

However, if the actual—not the potential—physiological performance of soils should be related to specific microbial activities, it is not enough to determine the amount of the corresponding genes on DNA basis. Further investigations including the transcription or expression level are highly needed. Approaches for the extraction and analysis of mRNA (Sharma et al., 2006, 2007a) and proteins (Roberts and Jones, 2008) have been developed in recent years. Mainly the short half-life of mRNA is a major methodological and conceptual problem, even if for most genes in soil half times >5 h can be assumed. Therefore, the analysis of mRNA might be useful but is more a snapshot of an actual status at the time of sampling and varies highly in time and space. At the protein level, it is important that a targeted approach for the detection of individual proteins is used, since a total extraction of all proteins from soil is still extremely difficult (Hartmann et al., 2005; Nannipieri, 2006). Overall, however, a collection of all three levels of the genome–transcriptome–proteome is needed to link processes and fluxes in soils to microbial activity pattern and performance (Figure 24.6).

24.3 Soil Fungi

R. Greg Thorn

24.3.1 Introduction

Soil is all of the unconsolidated mineral and organic materials on the ground surface that is differentiated from the parent materials below and the unincorporated and undigested litter above by the biological activities of fungi, bacteria, invertebrates, and other soil organisms. This definition includes the L, F, H, and O organic horizons and the mineral horizons from A to C (Fanning and Balluff, 1989; Bridges, 1997) and could be expanded to include the aerial "soil" that forms on the surfaces of trees that are covered with mosses, lichens, and vascular plant epiphytes in humid regions (Nadkarni et al., 2004; Enloe et al., 2006). The nature of the inorganic parent material and the activities of plants and soil organisms together make a soil what it is. The dominant soil

organisms, both in terms of processes and biomass, are the fungi (de Boer et al., 2005; Joergensen and Wichern, 2008). It is difficult to overemphasize the importance of fungi in soil. In many soils, the biomass of fungi exceeds that of all other soil organisms combined (excluding plant roots) by a factor of 10–1. In soil, as elsewhere, the primary and best known role of fungi is the decomposition and mineralization of complex, recalcitrant compounds of plant and animal origins, such as cellulose, hemicellulose, lignin, and chitin (Rayner and Boddy, 1988; Schwarze et al., 2004; Boddy et al., 2007). Other major roles of soil fungi include their involvements in beneficial and detrimental symbioses with plant roots. These range from the mutually beneficial mycorrhizae that enable land plants to exist in the face of nutrient and water limitations and other stresses to the plant pathogens that annually cause billions of dollars in losses to world crops (Agrios, 2004; Smith and Read, 2008; Section 24.4). Less well known, but possibly of great importance in the functioning of soil ecosystems, are the many connections made by fungi between virtually all soil organisms, at all trophic levels (Thorn, 1997).

The purpose of this chapter is to provide a brief introduction to the modern classification of those organisms that are fungi or resemble true fungi, what these organisms do, and modern methods for the analysis of their presence and activity. A selection of more detailed references is included for particular aspects.

24.3.2 The Diversity of Fungi and Fungus-Like Organisms and Their Roles in Soil

Although the strict definition of mycology is the study of fungi, many of the organisms that mycologists have studied are outside of the Kingdom Fungi (Figure 24.7). These organisms are united by a suite of fungus-like characteristics: they are non-photosynthetic chemoheterotrophs that reproduce by spores. Many have extracellular digestion and absorptive nutrition and most have a filamentous growth form. This broad definition has included the filamentous bacteria (actinomycetes), slime molds that are more closely related to the amoebae, "water molds" that prove to be achlorophyllous heterokont algae, and true members of the Kingdom Fungi. True fungi are the closest relatives of the Animal Kingdom (not of plants), and fungi and animals are derived from the slime molds. Fungi can be divided among five phyla: the Chytridiomycota, Zygomycota, Glomeromycota, Ascomycota, and Basidiomycota, although the Chytridiomycota and Zygomycota as currently defined are not monophyletic groups (Schüßler et al., 2001; Hibbett et al., 2007).

24.3.2.1 Actinomycetes

These prokaryotic organisms, although sometimes called the "ray fungi," are bacteria (=Eubacteria), not fungi. They form a part of the high GC subdivision of the Gram-positive lineage, along with nonfilamentous, important soil bacteria such as *Arthrobacter* and human and animal pathogens such as *Mycobacterium* (Woese, 1987; Embley and Stackebrandt, 1994; Anderson and Wellington, 2001; Zhi et al., 2009). However, as the trivial name actinomycetes suggests (the ending-mycetes
FIGURE 24.7 A phylogenetic tree indicating the place of various groups of fungi and fungus-like organisms (indicated in bold font), based on Archibald and Keeling (2004), Lutzoni et al. (2004), and Keeling et al. (2005). Many groups of organisms are left out (e.g., actinomycetes, not shown, are members of domain Bacteria), branch lengths are not proportional to sequence divergence, and the tree is not rooted. The relationships of the three domains Archaea, Bacteria, and Eukarya (Wheelis et al., 1992) are not resolved.

refers to fungi), they possess a number of fungus-like characteristics, including the hyphal (tubular) growth form, the production of extracellular enzymes (including cellulases but not lignin peroxidases; Ball and Trigo, 1997; Mason et al., 2001), and absorptive nutrition. These characteristics combine to make them important decomposers of organic particles in soil (Kirby, 2006; Elfstrand et al., 2008; Jayasinghe and Parkinson, 2008). Certain thermophilic actinomycetes are predominant in high-temperature composts (40°C–60°C), and are important in the formation of composted substrate for commercial cultivation of the button mushroom, *Agaricus brunnescens* (Fermor and Grant, 1985; Savoie, 1998). Like the Gram-negative rhizobia and selected cyanobacteria, actinomycetes in the genus *Frankia* form nitrogen-fixing symbioses with the roots of various woody plants (Jeong et al., 1999; Wall, 2000; Vessey et al., 2004; Bothe et al., 2007). Nitrogen fixation by fungi or other eukaryotes have not been convincingly demonstrated (Postgate, 1998). Saprotrophic actinomycetes are abundant in soil (Williams et al., 1984) and produce the compound geosmin, which is responsible for the characteristic odor of freshly tilled soil (Gerber and Lechevalier, 1965). Actinomycetes, particularly *Streptomyces* spp., are commonly recovered during the isolation of soil fungi but are readily recognized by their tufted growth form and extremely fine (<0.5 μm) hyphae. Media for the selective isolation of actinomycetes frequently make use of the antifungal antibiotic cycloheximide (actidione), and antibacterial antibiotics to which actinomycetes are tolerant, and may contain colloidal chitin as the sole carbon and nitrogen source (Goodfellow and Cross, 1974). There is no realistic estimate available of the number of species of actinomycetes inhabiting soil. However, over 670 described species of the important genera *Actinomyces*, *Frankia*, *Geodermatophilus*, *Streptomyces*, *Streptosporangium*, *Streptoverticillium*, and *Thermoactinomyces* are accepted in the *List of Prokaryotic names with Standing in Nomenclature* (Euzéby, 2009; http://www.bacterio.cict.fr/), and this is likely to be a tremendous underestimate of the real diversity of these organisms in soil (cf. Stach et al., 2003).

24.3.2.2 Protozoan "Fungi"

The fungus-like protists include the slime molds and their relatives in the phylum Mycetozoa (myxomycetes or myxogastria, dictyostelids, and protostelids), plus plasmodiophorids of the phylum Cercozoa, and acrasids of the phylum Percolozoa (Alexopoulos et al., 1996; Archibald and Keeling, 2004; Kirk et al., 2008). The phylum name Mycetozoa (fungus animals) refers to their mix of fungus-like and animal-like characters: reproduction by spores and ingestion of food by phagocytosis. The acrasids, dictyostelids, protostelids, and myxomycetes occur in soil as amoebae, and the latter may be abundant in the root rhizosphere (Amewowor and Madelin, 1991). These amoeba-like cells may aggregate to form motile "slime stages" that are multicellular pseudoplasmodia (in dictyostelids) or multinucleate plasmodia (in myxomycetes) that continue to feed on bacteria, other microbes, and small organic particles; those of certain myxomycetes can be conspicuous on lawns and garden beds of wood-chip mulch (Martin and Alexopoulos, 1969; Raper, 1984; Stephenson and Stempen, 1994). The plasmodiophoromycetes (Phytomyxea) include important root pathogens of cultivated crucifers (cabbage and cole crops) and potatoes, and may also serve as vectors of plant–pathogenic viruses (Braselton, 2001). Owing to their abundance in soils and their lack of cell walls during their trophic phase, the protistan "fungi" may contribute a substantial proportion of the eukaryotic DNA recovered during lysis procedures for the isolation of bacterial DNA from soil. This group includes 1165 described species, many of which live in habitats other than soil, such as rotting wood, bark, and dung (Kirk et al., 2008).

24.3.2.3 Stramenopile "Fungi"

Fungus-like members of the Kingdom Stramenopila (or Chromista) include the Oomycota and Hyphochytriomycota, which have often gone by the name of "water molds" (Alexopoulos et al., 1996; Dick, 2001a, 2001b; Fuller, 2001). Like the actinomycetes, the oomycetes (or peronosporomycetes) have a number of fungus-like characteristics, including the hyphal growth form, the production of extracellular enzymes, and absorptive nutrition (Dick, 2001b). Unlike most true fungi, members of both the oomycota and hyphochytriomycota have motile stages known as zoospores. These are powered by two different types of flagella, the whiplash and the tinsel flagellum, in common with the motile stages of chromistan algae (the diatoms and the golden and brown algae). The hyphochytriomycota are a small group known primarily as parasites of oomycota, but the oomycota are a fairly large group that include the important soilborne plant pathogens *Pythium* and *Phytophthora* (Buczacki, 1983; Martin, 1992; Erwin and Ribeiro, 1996; Arcate et al., 2006). There are approximately 1000 described species of stramenopile "fungi" of which perhaps half occur in freshwater and marine habitats (Kirk et al., 2008).

24.3.2.4 Kingdom Fungi, Phylum Chytridiomycota

Soil chytrids are a relatively small group, including plant pathogens such as *Synchytrium* and *Olpidium*, nematode parasites such as *Catenaria*, parasites of algae such as *Chytridium*, and saprobes such as *Allomyces* and *Chytriomyces* (Barr, 2001; James et al., 2006b). The soil chytrids possess motile zoospores powered by a single, posterior flagellum, and are thought to be close to the common ancestor of fungi and animals. Phylogenetic analyses that have included more than one representative of each of the chytrids and zygomycetes have indicated that the chytrids may form a monophyletic group, splitting the zygomycetes (Van de Peer and De Wachter, 1997) or that both groups may be polyphyletic and interspersed one among the other (Nagahama et al., 1995; James et al., 2006b). Together, the chytrids and zygomycetes differ considerably from the Ascomycota and Basidiomycota in that they are typically coenocytic, with multiple genetically different nuclei per cell, whereas the Ascomycota and Basidiomycota typically have uninucleate primary mycelia and binucleate (dikaryotic) secondary mycelia. Many of the approximately 700 described species of chytrids (Kirk et al., 2008) occur in freshwater or marine environments, and I know of no estimate of the number of species occurring in soil.

24.3.2.5 Kingdom Fungi, Phylum Zygomycota

Soil-inhabiting members of the Zygomycota belong in two groups of very different morphology and ecology: the predominantly saprobic zygomycetes (Mucorales and relatives) and the Zoopagales, Kickxellales, and Entomophthorales, which are parasitic on insects and other invertebrates, fungi, and humans (O'Donnell, 1979; Humber, 1989; Alexopoulos et al., 1996; Benny et al., 2001; White et al., 2006; Kirk et al., 2008). A third group formerly treated as the Glomerales (misspelled Glomales) has since been shown to represent an independent phylum, Glomeromycota (Schüßler et al., 2001; see later). As mentioned above, recent phylogenetic analyses that have included multiple examples of both chytrids and Zygomycota suggest that neither forms a monophyletic group. The saprobic and mycoparasitic zygomycetes (Mucorales and relatives) are more basal and cluster together with some or all of the chytrids, while the Glomeromycota appear to be the sister group to the "higher fungi" (subphylum Dikarya, Hibbett et al., 2007), the Ascomycota and Basidiomycota (Nagahama et al., 1995; James et al., 2006a; Figure 24.7). However, all of these groups share general morphological features such as broad, tubular, thin-walled hyphae, the coenocytic condition, and positive (red) staining of their hyphal walls with diazonium blue B (Summerbell, 1985; Prillinger et al., 2002).

In the earlier literature, the saprobic Mucorales were often referred to as "sugar fungi." The accompanying view held that these organisms are rapid colonists making use of the soluble sugars before secondary colonists become established during the succession of different fungi on rich and freshly deposited substrates such as dung and fallen fruits (Garrett, 1963). In reality, the rapid appearance of Mucorales on such substrates reflects their rapid rates of growth and sporulation; in many cases, the "secondary colonists" are already there and digesting the more recalcitrant substrates but are slower to sporulate and come to our notice (Pugh, 1974; Cooke and Rayner, 1984). Still, the term "sugar fungi" accurately portrays the typical growth substrate of these fungi. They are not noted for their extracellular degradative enzymes and may frequently depend on the breakdown products provided by lignocellulose-degrading ascomycetes or basidiomycetes (Cooke and Rayner, 1984). From here, it may have been a short step to direct, biotrophic parasitism of the decomposer fungi, a nutritional mode found among some Mucorales and related groups (O'Donnell, 1979; Benny et al., 2001). Of the 1065 described species of Zygomycota (including Entomophthorales, Kickxellales, Mucorales, and Zoopagales) accepted in the *Dictionary of the Fungi* (Kirk et al., 2008), the majority might be found in soil or close to soil in various organic substrates.

24.3.2.6 Kingdom Fungi, Phylum Glomeromycota

The phylum Glomeromycota contains a single order, Glomerales (formerly misspelled Glomales and treated within the Zygomycota) (Morton, 1988; Morton and Benny, 1990; Schüßler et al., 2001; Redecker and Raab, 2006; http://www.lrz-muenchen.de/~schuessler/amphylo/). It appears that this lineage goes back at least to the early Cambrian, when they may have been symbiotic with cyanobacteria and, later, with the ancestors of modern land plants (Pirozynski and Malloch, 1975). These are arguably among the most important of all of the fungi: Approximately 80% of the world's land plants depend upon mycorrhizal symbioses with these fungi for survival in soils that are nutrient-limiting or prone to drought or other stresses (Malloch et al., 1980; van der Heijden et al., 1998; Selosse et al., 2004; de Boer et al., 2005; Smith and Read, 2008; Section 24.4). As in chytrids

and zygomycetes, their hyphae are coenocytic, and recent analyses have shown that many of the nuclei in a single spore may be genetically distinct (Jansa et al., 2002; Sanders, 2002). *Geosiphon*, a sac-like soil organism that forms an endosymbiosis with a photosynthetic cyanobacterium (the cyanobacterium is inside the *Geosiphon*) is a basal member of the Glomeromycota (Gehrig et al., 1996; Schüßler, 2002). This endosymbiosis is most likely very old: the origin of the Glomeromycota is thought to be some 350–550 million years ago based on fossil evidence (Pirozynski, 1981; Pirozynski and Dalpé, 1989) or DNA sequence divergence (Berbee and Taylor, 1993; Simon et al., 1993; Taylor and Berbee, 2006), and the cyanobacteria date back to 2.9–3.4 billion years before present (Schopf, 1993). Approximately 215 species of Glomeromycota in 14 genera are known (http://www.lrz-muenchen.de/~schuessler/amphylo/), and their ability to form symbioses with a far greater diversity of land plants remains an interesting puzzle. It is possible that the complex nuclear makeup of individuals in this group provides the genetic variation required to achieve symbioses with such a broad range of host plants and in a broad range of habitats. However, some studies have shown that there is more host or habitat specificity than has generally been recognized, perhaps a function of identifications based on their very limited morphology (Lovelock et al., 2003; Vandenkoornhuyse et al., 2003; Sykorová et al., 2007; Appoloni et al., 2008). If true, appropriate species of these fungi could be vital in survival or restoration of rare or endangered vascular plant species, and the community of arbuscular mycorrhizal fungi determines plant community diversity and productivity (van der Heijden et al., 1998).

24.3.2.7 Kingdom Fungi, Phylum Ascomycota (Including Most Yeasts and Most Asexual Forms Previously Included in the "Deuteromycetes")

The Ascomycota include species of diverse nutritional modes, from saprotrophs through plant and animal pathogens, mycoparasites, and mycorrhizal associates. The Ascomycota include fungi that reproduce sexually through the production of meiotic spores in a cell called an ascus (plural asci), as well as their phylogenetic relatives that are only known to reproduce asexually or rarely sexually. The inclusion of asexual relatives may seem obvious to the nonmycological reader, but the tradition in mycology has been to recognize separate taxa for the sexual and asexual forms (e.g., Webster, 1981; Hawksworth et al., 1983). Filamentous asexual forms have been called imperfect fungi, fungi imperfecti, deuteromycetes, hyphomycetes, or molds. There have been separate names and classifications all the way from genus and species (e.g., asexual *Aspergillus nidulans* versus sexual *Emericella nidulans*) up to phylum ("Deuteromycota" versus Ascomycota, Margulis and Schwartz, 1988). The vast majority of deuteromycete species have not been connected with any sexual state (indeed, it is thought that many may not have a sexual state) (Seifert and Gams, 2001; Domsch et al., 2007). However, there are a number of morphological, physiological, and molecular criteria by which these fungi can be recognized as belonging to

the Ascomycota (see later), so there seems little justification for retaining separate, artificial classifications above the level of the genus. *Aspergillus*, *Cladosporium*, *Fusarium*, and *Penicillium* will remain familiar genera of soil fungi, even if some species are connected with sexual states that have different names. The Ascomycota also include the majority of species of the yeasts, predominantly cellular (nonfilamentous) organisms that usually reproduce asexually by budding or fission (Kurtzman and Fell, 1998; Barnett et al., 2000). In yeasts, too, species known only to reproduce asexually are barred from genera typified by species that reproduce sexually. The genus *Candida* consists of a polyphyletic assemblage of asexual species of diverse affinities. However, the cellular growth form of yeasts is an adaptation to life in moist or liquid environments, and some members of the Basidiomycota have independently developed the yeast life form (see later). Thus, yeasts and molds are artificial categories of fungi, useful to describe their appearance and ecology but not their classification.

A particular disadvantage of this system has been that a single genus name used for asexual forms (e.g., *Sclerotium* or *Rhizoctonia*) may include species of both Ascomycota and Basidiomycota: two phyla in one genus. Likewise, maintenance of a separate class Deuteromycetes has hidden the fact that we do not know the correct phylum for many of the species included. For instance, the economically important fungus causing cotton root rot, *Phymatotrichopsis omnivora*, is only known to reproduce asexually. Despite ultrastructural and physiological evidence to the contrary, it was widely reported as an asexual member of the Basidiomycota until DNA sequence analyses placed it in the family Rhizinaceae (Pezizales) of the Ascomycota (Marek et al., 2009). With new knowledge from ultrastructural, physiological, and molecular studies, this situation is gradually improving; the genus *Rhizoctonia* has recently been subdivided along phylogenetic lines (Roberts, 1999). Recent molecular phylogenetic analyses have included the asexual forms among their sexually reproducing relatives and have greatly improved our level of knowledge of the broad relationships within the Ascomycota (Blackwell et al., 2007; see http://www.fieldmuseum.org/myconet/outline.asp).

The Ascomycota and their asexual relatives are certainly the largest group of fungi, with over 64,000 described species (Kirk et al., 2008). About 20,000 described species form lichens: stable symbiotic associations between fungi and green algae or cyanobacteria, in which the fungal partner (mycobiont) forms a characteristic structure called a thallus that encloses and protects the alga or cyanobacterium (photobiont) (Hawksworth, 1988; Ahmadjian, 1993; Grube and Hawksworth, 2007). As with mycorrhizae, the lichen habit or symbiosis has multiple separate evolutionary origins amongst Ascomycota and Basidiomycota. These separate origins, long recognized on the basis of morphology, are also "suggested" by molecular phylogenetic analysis (Gargas et al., 1995). Lichens are important in soil formation by the colonization and physicochemical degradation of bare rocks (Hale, 1983; Nash, 2008) and form part of the cryptogamic crusts stabilizing and providing nutrients to desert soils (West, 1990;

Johansen, 1993; Belnap et al., 2001), but they are not normally considered soil fungi. Many other species of Ascomycota are parasites or endophytes of aerial plant parts, are human or animal pathogens, or inhabit dung or other specialized substrates. Some of these have a soilborne stage or a significant reservoir in soil. Perhaps 15,000 or more described species of Ascomycota might be found in soil or in litter and other organic substrates on soil.

Persons isolating fungi from substrates such as soil, rotting wood or litter, or diseased plants or animals frequently recover cultures of morphologically undistinguished fungi that lack the sexual reproductive structures necessary to identify them as members of the Ascomycota or Basidiomycota. These fungi may sporulate asexually but belong to a group that has never been connected with any sexual state, or may be nonsporulating in pure culture. The latter, "sterile" forms are often referred to in the literature as sterile white mycelium, sterile dark mycelium, or *mycelium radicis atrovirens* (Latin for greenish black mycelium from roots). These names are unhelpful, in terms of physiological, taxonomic, and ecological precision, and should no longer be necessary or accepted in publication, given the many tools with which we can now quite simply make a more accurate identification.

Hyphae of Ascomycota have simple septal pores; that is, their septa thin to a circular pore that provides a cytoplasmic connection between adjacent cells. Almost all members of the Basidiomycota that grow in culture as filamentous colonies (not yeasts) have what are called dolipore septa, a donut-like thickening around the septal pore that may be surrounded by a perforate or imperforate, membranous septal pore cap (Wells, 1978, 1994; Moore, 1985). Some Basidiomycota also form clamp connections (looping connections across septa) in their dikaryotic mycelia, and these are diagnostic if present. For those fungi without clamp connections, the dolipore septum or lack of it can usually be seen with a good light microscope in light-colored hyphae more than 1 μm in diameter if they are stained with trypan blue (Sneh et al., 1991) or with Congo red in an aqueous solution of ammonia or sodium dodecyl sulfate (Nawawi et al., 1977; Clemençon, 1998). Laser confocal microscopy should also provide a good method for detection of dolipore or simple septal pores in living or fixed materials, particularly if cell walls are stained with a fluorescent dye such as calcofluor white. Dolipore septa and simple septal pores are readily identified with transmission electron microscopy (TEM) in appropriate sections. If material is fixed, sectioned, and examined with TEM, Ascomycota can usually be distinguished from Basidiomycota even if septal pores are not seen in the section or sections examined. Most Ascomycota have bilayered hyphal walls, with a narrow, electron-dense outer layer and a broad, pale inner layer. In contrast, most Basidiomycota have multilamellate hyphal walls, with multiple narrow light and dark layers as seen in TEM (Bracker, 1967; Alexopoulos et al., 1996). The hyphal walls of Ascomycota and Basidiomycota (especially yeasts, and less dependably filamentous forms) also differ in their reaction to staining with diazonium blue B. The hyphal walls of Basidiomycota stain red or

purplish (a pretreatment with KOH is necessary for filamentous forms), whereas the walls of most Ascomycota are nonstaining (Hagler and Ahearn, 1981; Summerbell, 1985). As mentioned above, hyphae of Glomeromycota and Zygomycota also stain with diazonium blue B, but these can easily be distinguished from members of the Basidiomycota by their large diameter and coenocytic nature. Physiologically, cultures can often be determined as Ascomycota or Basidiomycota by their pattern of tolerance or sensitivity to sodium chloride, benomyl, and cycloheximide (Hutchison, 1990). Finally, great progress has been made in the extraction and sequencing of fungal DNA, enabling the rapid and certain identification—at least at the phylum level—of an unknown strain by comparison with available sequences of known strains (e.g., Bruns et al., 1991; Marek et al., 2009).

24.3.2.8 Kingdom Fungi, Phylum Basidiomycota (Including Some Yeasts and Some Asexual Forms Previously Included in the "Deuteromycetes")

The Basidiomycota include two of the most important groups of soil fungi: species forming ectomycorrhizae of forest trees (Smith and Read, 2008; Section 24.4), and species that are the dominant decay organisms of plant polymers such as lignin, hemicellulose, and cellulose (Rayner and Boddy, 1988; Boddy et al., 2007). A few basidiomycetes, such as *Rhizoctonia solani*, are very important plant pathogens of field and forage crops ranging from wheat to rice to alfalfa. Others are root pathogens of tropical tree crops such as rubber and oil palms, or are root pathogens or cause rot and butt rots of tropical and temperate forest trees and turf (Ploetz et al., 1994; Roberts, 1999; Smiley et al., 2005). The Ascomycota and their asexual relatives are usually thought to be the major group of soil fungi, both in number of species and in biomass. This may be true in agricultural soils and in native tropical soils, but in many temperate and boreal forest soils, the basidiomycetes probably outnumber and outweigh the ascomycetes in at least the organic-rich soil horizons (Frankland, 1982; Entry et al., 1992). Many form extensive mycelia with considerable biomass. The most famous of these is *Armillaria*, the "humongous fungus" of which one individual mycelium was calculated to occupy 15 ha and have a weight of 10 Mg (Smith et al., 1992); another individual *Armillaria* thought to occupy 40 ha has been reported (Shaw and Roth, 1976). Clearly, the Basidiomycota include the fungi with the best ligninolytic abilities (Orth et al., 1993; Worrall et al., 1997; Baldrian, 2008) and are therefore likely to be the most important in decomposition of plant litter in most soils. Approximately 10,000 of the over 31,000 described species of Basidiomycota may be found in soil or litter (Kirk et al., 2008).

As with the situation in the Ascomycota, a number of asexual or predominantly asexual fungi belong in the Basidiomycota. Their natural relationships have been hidden (perhaps especially to nonmycologists) by their inclusion in the artificial class "Deuteromycetes." Formerly orphaned fungi include "molds" such as the *Sporotrichum* (=*Chrysosporium*) state of

Phanerochaete chrysosporium and many yeasts frequently encountered in soil, such as *Rhodotorula*. Recent molecular phylogenetic analyses of Basidiomycota (summarized in, e.g., Hibbett and Thorn, 2001; Hibbett et al., 2007) have greatly improved our knowledge of the relationships of these fungi and provide a framework into which the asexual forms and unidentified isolates from soil or mycorrhizae may be placed and identified (Bruns et al., 1998; Kõljalg et al., 2005; http://unite.ut.ee/).

Despite their numbers and biomass in soil, the Basidiomycota are rarely recovered in surveys of soil fungi based on isolation into culture, because few produce significant numbers of propagules in soil in the way that the asexual Ascomycota do. On isolation plates, the few hyphal propagules of Basidiomycota are tremendously outnumbered by mold spores and outcompeted by the more rapidly growing mold fungi. Because of this, the Basidiomycota remain the "missing link" in soil mycology (Chesters, 1949), 60 years after Chesters first made that claim. In order to overcome our inability to routinely isolate decomposer basidiomycetes from soil, Thorn et al. (1996) developed a method of plating washed organic particles from soil on a medium made selective for basidiomycetes with benomyl (Edgington et al., 1971; Worrall, 1991; Johnson, 1994) and with guaiacol as an indicator of laccase(s) and peroxidase(s) (these enzymes convert colorless guaiacol to a deep red quinone). The addition of dicloran (2,6-dichloro-4-nitroaniline; no longer widely available) to the medium should provide control of Mucorales (which are tolerant to benomyl), for soils or litters in which these fungi are a problem (Worrall, 1991); hymexazol (3-hydroxy-5-methylisoxazole) would be an alternative (Tsao and Guy, 1977). The use of these or other semiselective inhibitors in soil (for instance, to assay the activities of particular taxonomic groups of fungi) is beset with complications that may lessen their usefulness, such as nontarget effects and quenching of the inhibitory effects of the selected compound by physical or chemical components of soil (Nannipieri et al., 2003).

24.3.3 Methods for the Characterization of Communities and Activities of Soil Fungi

Among the methods available for the characterization of communities and activities of soil fungi are direct counts (Bloem et al., 1995) and immunological detection (Frankland, 1984; Clausen, 1997), differential inhibition with antibacterial and antifungal biocides and measurement of CO_2 evolution or other indicators of physiological activity (Anderson and Domsch, 1975; Kjøller and Struwe, 1982; Bailey et al., 2003), chloroform fumigation and incubation or extraction methods for total microbial biomass (Harris et al., 1997), incorporation of ^{13}C-labeled substrates into biomarkers such as ergosterol (Boschker et al., 1998; Baath 2001; Neufeld et al., 2007), activity stains applied to fungi in soil smears (Tsuji et al., 1995; Li et al., 2004), assays on enzymes extracted from soil and litter (Wood, 1979; Savoie, 1998; Osono, 2007), isolation and quantitation of fungal biomarkers such as ergosterol or chitin-derived glucosamine (Swift, 1973;

Tunlid and White, 1992; Zhao et al., 2005), isolation of fungi into culture, and isolation and characterization of fungal DNA or RNA from soil. A brief overview of methods for isolating fungi from soil and isolation and characterization of soil fungal DNA and RNA are all that can be included here.

24.3.3.1 Methods for Isolating Fungi from Soil

Methods for the isolation into culture of various fungi from soil have recently been compiled and reviewed (see Mueller et al., 2004). Keys for the identification of common genera and species of soil fungi of temperate areas are available (e.g., Domsch et al., 2007), but identification of many isolates from tropical soils or from temperate or tropical litter must be sought in the large mycological literature, to which Kirk et al. (2008) provide an entry. In choosing a method for isolating fungi from soil, one should first define the objective; is it to obtain a complete list for one sample, or a suite of predominant species by which to compare two or more samples, or to recover a specific species or ecological group of interest? If it is to obtain a "complete" list, be prepared for a challenge: Christensen (1989), using just one method and medium, found that 8–15 previously unseen species of microfungi were added with every 100 incremental isolates past 1100. No one method, medium, or incubation temperature will recover all fungi in any sample (Carreiro and Koske, 1992). A number of sources discuss methods and media for the selective recovery of particular groups of fungi (see Mueller et al., 2004). The greatest difficulty with any of these methods is the inability to relate the species and numbers of isolates obtained to the identities and importance of fungi in the native soil.

24.3.3.2 Isolation and Characterization of Nucleic Acids from Soil

Methods for the isolation of DNA and RNA from soil have seen great improvements in recent years, with off-the-shelf kits yielding nucleic acids of good quality (e.g., suitable for PCR) much more rapidly and reliably than laborious techniques that were common in the 1990s (e.g., Holben et al., 1988). Most early studies of soil DNA were directed toward characterization of the soil bacterial community, but in recent years, the field has really opened wide: studies of fungal community membership (e.g., O'Brien et al., 2005; Lynch and Thorn, 2006) have been joined by studies detecting particular genes (Section 28.1) and gene expression (Section 28.2). Individual fungal taxa of interest (e.g., plant or human pathogens) can be detected by probing with taxon-specific probes (Bruns and Gardes, 1993; McArthur et al., 2001), amplification using taxon-specific primers (PCR-based detection assays; Gardes and Bruns, 1993; Lievens et al., 2006; van der Linde et al., 2008), or by using the extracted nucleic acids to probe taxonomic arrays of oligonucleotides bound on glass slides (microarrays) or nylon membranes (macroarrays) (e.g., Tambong et al., 2006). The relative biomass of selected fungi in soil may be estimated using real-time PCR (qPCR; e.g., Landeweert et al., 2003). Community analyses have been done by PCR amplification of rRNA or other genes with conserved fungal primers (or broadly specific primers, e.g., Redecker, 2000; Lynch and Thorn, 2006;

Appoloni et al., 2008) and subsequent cloning and sequencing of amplified products (e.g., Vandenkoornhuyse et al., 2002; Martin and Rygiewicz, 2005; O'Brien et al., 2005). Community analyses based on banding patterns (e.g., RFLP or DGGE) of amplified community DNA, without accompanying sequence data that allow identification of the community members, are not recommended because of the inability to compare between sites or studies. "Next generation" sequencing using 454 or Titanium pyrosequencing platforms (e.g., Roesch et al., 2007; Tringea and Hugenholtz, 2008) produces millions of short (30 to perhaps 200 bp) sequences from a sample, permitting much broader and semiquantitative analyses of fungal communities from soil, litter, or other complex substrates. These approaches allow us to increase the sample size of fungal communities investigated and may better answer the question of what proportion of the fungal community can be isolated into culture. The future of soil mycology just got more interesting, again.

24.3.4 Conclusions

Two facts became apparent as I revised this review, first written about 10 years ago. First, there have been tremendous changes in the classification (and, as a result, naming) of fungi and fungus-like organisms at all levels from their Kingdom placement to their species names. An outline of the higher classification of Fungi has been published (Hibbett et al., 2007), and these changes have been included in the latest edition of the *Dictionary of the Fungi* (Kirk et al., 2008). The latter also has separate sections for fungus-like organisms belonging in the Heterokonta or "Protozoa" (Kirk et al., 2008). It will be some time before these changes make it into textbooks of mycology, let alone those for plant pathology, botany, or general biology. However, as in all fields of biology, a classification that more closely reflects the evolutionary history of the organisms will be more predictive and useful than our historical classifications that were misled by morphological convergences.

Secondly, new molecular techniques are allowing a rapid acquisition of knowledge about the composition and functioning of complex fungal communities that was simply unattainable even recently. Applied critically, these new methods are rejuvenating mycology and bringing the fundamental importance of fungi to the attention of ecologists and soil biologists. It is time for fungi to be given their due.

24.4 Mycorrhizae

Raffaella Balestrini

Valeria Bianciotto

Paola Bonfante

24.4.1 Introduction

Mycorrhizal fungi are specialized root symbionts that engage in intimate association with a great diversity of plants (Smith and Read, 2008; Bonfante and Genre, 2010). The term mycorrhiza implies an association of fungi with roots (from the Greek "mycos," meaning fungus and "rhiza," meaning root), relationships, called mycorrhizal associations. These are also found between fungi and the underground gametophytes of many bryophytes and pteridophytes, as well as the sporophytes of most pteridophytes and the roots of seed plants (Bonfante and Genre, 2008; Smith and Read, 2008). The most understood function of such symbioses concerns the improvement of plant mineral nutrient acquisition, in exchange for carbon compounds, which results in positive host growth responses. Mycorrhizal fungi can also perform many other significant roles, including protection of the plant from biotic and abiotic stress, for instance, by altering host environmental tolerances to water deficit or pollutants or reducing susceptibility to soilborne pathogens (Aroca et al., 2007; Smith and Read, 2008).

Structures similar to arbuscular mycorrhiza have been observed in plant fossils from the Early Devonian (Selosse and Le Tacon, 1998), whereas fossil ectomycorrhiza have been found in the middle Eocene (Le Page et al., 1997). The variety of mycorrhizal associations established between plants and fungi has been divided into seven categories (arbuscular mycorrhiza, ectomycorrhiza, ectendomycorrhiza, arbutoid mycorrhiza, monotropoid mycorrhiza, ericoid mycorrhiza, orchid mycorrhiza—Table 24.4), primarily on the basis of the structural characteristics of the symbiotic interfaces and the taxonomic identity of the symbionts (Smith and Read, 2008).

Mycorrhizal associations are found in most annual and perennial plants. About two-thirds of these plants, mostly herbaceous species belonging to crops (e.g., maize and rice), are symbiotic with arbuscular mycorrhizal (AM) fungi. Ericoid mycorrhizae are ecologically important as efficient organic matter (OM) degraders but are mainly restricted to heathlands (Read and Perez-Moreno, 2003). While ectomycorrhizae (ECM) are made up of a relatively small number of plants (about 8000 species, see Section 24.4.2.2), their ecological importance is amplified by their extensive occupancy of biomes (Martin, 2007). These associations dominate in boreal, temperate, Mediterranean and some subtropical forest ecosystems (Read and Perez-Moreno, 2003). Pinaceae, members of which form the major component of the vast boreal forests in the northern hemisphere, and Fagaceae, dominants or codominants of the northern and some southern hemisphere temperate forests, as well as tropical forests in Southeast Asia, are predominantly ectomycorrhizal species (Smith and Read, 2008). Some genera of shrubs are also routinely found to be ECM (i.e., Cistaceae). These plant species, through the symbioses with ECM fungi, have been able to acquire metabolic capabilities that in turn have allowed otherwise unavailable ecological niches to be utilized.

This chapter focuses on the most relevant aspects of mycorrhizal symbioses, focusing on the nutrient exchanges between the partners. It also provides insights into new approaches that can be used to study these fungi directly in the field (metagenomics or environmental genomics).

24.4.2 Mycorrhizal Fungi: A Heterogeneous Group of Soil Fungi

24.4.2.1 Arbuscular Mycorrhizal Fungi

The most ancient mycorrhizal fungi, on the basis of evidence from paleobotanical studies and the analysis of rDNA-based phylogenies, are those that form arbuscular mycorrhizae. Their earliest fossil record dates back to the Ordovician, 460 million

TABLE 24.4   Characteristics of the Several Mycorrhizal Types

Kinds of Mycorrhizae	Arbuscular Mycorrhizae	Ectomycorrhizae	Ericoid Mycorrhizae	Orchid Mycorrhizae	Ecto-Endomycorrhizae	Arbutoid Mycorrhizae	Monotropoid Mycorrhizae
Mycobiont	Glomeromycota	Basidiomycota Ascomycota (Zygomycetes)	Ascomycota	Basidiomycota	Basidiomycota Ascomycota	Basidiomycota	Basidiomycota
Phytobiont	Bryophyta Pteridophyta Gymnospermae Angiospermae	Gymnospermae Angiospermae	Ericales Byophyta	Orchidales	Gymnospermae Angiospermae	Ericales	Monotropoideae
Intracellular structures	+	−	+	+	+	+	+
Fungal mantle	−	+	−	−	±	±	+
Hartig net	−	+	−	−	+	+	+

years ago (Redecker et al., 2000), but molecular clock-based inferences estimate their origin as much earlier (Tehler et al., 2000; Berbee and Taylor, 2001; Schüβler et al., 2001), possibly as far back as between 1200 and 1400 Ma ago (Heckman et al., 2001). Thus, it has been hypothesized that symbiosis played a key role in the colonization of lands by plants (Taylor et al., 1995; Phipps and Taylor, 1996). AM fungi have been accommodated inside the phylum Glomeromycota, which is a sister clade to Asco- and Basidiomycota (Schüβler et al., 2001), on the basis of the 18S ribosomal gene sequences. More information is required to further support the definition of this phylum, and to clarify evolutionary patterns within the group, although information from different genomic loci/genes is continuously being collected (e.g., Helgason et al., 2003; Corradi et al., 2004; van der Heijden et al., 2004; Da Silva et al., 2006; Lee and Young, 2009).

Glomeromycota were considered a species-poor group, with about 214 species recognized by conventional spore-based morphology, based on a traditional, morphological species concept. Recently, new taxa have been identified and have been named *Ambispora*, *Intraspora*, *Pacispora*, *Kuklospora*, *Otospora*, and *Diversispora* (www.amf-phylogeny.com). Since these few morphospecies colonize about two-thirds of modern plants, arbuscular mycorrhizae appear to be not only the most ubiquitous and abundant terrestrial symbiosis but also nonspecific, with most AM fungi readily colonizing almost any susceptible plant species. Although some plant species enter into specialized relationships with only a few AM fungi, others appear to associate with as many as 20 different AM fungi, thus hosting very diverse AM fungal communities that include currently unknown taxa. Possible relationships between plant responsiveness to mycorrhiza and their selectivity toward specific AM fungi still have to be elucidated (van der Heijden, 2002). Their uniqueness is mirrored not only by this taxonomical status but also by their biological traits. AM fungi are obligate biotrophs; although AM fungal spores can germinate in the absence of host plants (presymbiotic phase), they depend on the establishment of symbiosis with a living photoautotrophic partner for the development of the intracellular colonization. This step is mandatory to complete the fungal life cycle and produce the next generation of spores. AM fungi are usually aseptate and coenocytic, with hundreds of nuclei sharing the same cytoplasm. At the same time, individual spores contain hundreds of nuclei and the question of how the different polymorphic DNA sequence variants are distributed between genomes or nuclei is still being studied (Parniske, 2008). Although there is no confirmed report of a sexual stage in the life cycle of AM fungi, Croll et al. (2008) have recently suggested that AMF are promiscuous, in the sense that an individual will form hyphal connections with several other members of the population and this creates the possibility of genetic exchanges. In particular, they have suggested that the exchange of nuclei among AMF isolates provides the opportunity for the fusion of genetically different nuclei and recombination (Croll et al., 2008; Croll and Sanders, 2009).

The sequencing of representative AM fungi, such as *Glomus intraradices* (Martin et al., 2008b), is currently in progress (http://www.jgi.doe.gov/DOEmicrobes2004.html), but due to the obligate biotrophic status of the fungus, it has encountered unexpected difficulties, rendering its achievement far from immediate (Martin et al., 2008b). Waiting for the production of a completely annotated and assembled *G. intraradices* genome, the increasing number of EST sequences obtained inside the *Glomus* Genome Consortium (GGC; INRA *Glomus* database: http://mycor.nancy.inra.fr/genomeResources.php) might provide new clues to strengthen our understanding of the biology of these fungi (Martin et al., 2008b). The assembly and annotation of the mitochondrial genome has been concluded, and it is already available in Gene Bank (Lee and Young, 2009; Young, 2009).

24.4.2.2 ECM Fungi

Ectomycorrhizal fungi are best known for their fruiting structures (e.g., toadstools), which often grow next to tree trunks in woodlands. However, morphological recognition has shown that ectomycorrhizal roots often contain fungi that cannot be linked to epigeous fruiting bodies (Anderson and Cairney, 2007). Most of the ECM plant species are trees or shrubs belonging to Betulaceae, Cistaceae, Dipterocarpaceae, Fagaceae,

Pinaceae, Myrtaceae, Salicaceae, and several tribes of Fabaceae (Martin, 2007). Although they represent a relatively small number of plants, the ecological importance of these symbioses is amplified by their extensive occupancy of biomes (Read and Perez-Moreno, 2003). Ectomycorrhizal fungi include at least 6000 species and, unlike AMs, ECM symbiosis involves a diverse range of fungi: a large number of basidiomycetes, some ascomycetes, and a handful of zygomycetes belonging to the genus *Endogone* (Smith and Read, 2008). Fossil evidence on macrofungi is very limited (Taylor and Taylor, 1997). It is likely that a period of rapid diversification of the basidiomycetes occurred in the Cretaceous, when plants with ECM associations became important. Ectomycorrhizal Basidiomycetous taxa, like Cortinariaceae, Boletales, Amanitaceae, and Russulaceae, probably originated in this period. The rapid diversification of these fungi continues to this day, driven by increasing host and habitat specificity (Brundrett, 2002). Unlike AM fungi, ECM fungi show conventional sexual mechanisms, with possibly a few exceptions such as the asexual widespread ascomycete *Cenococcum geophilum* (Girlanda et al., 2007). Ectomycorrhizal basidiomycetes and ascomycetes are not a phylogenetically separate group, but an assemblage of very different fungal species that have independently developed a symbiotic lifestyle over the past 130–180 million years (Hibbett et al., 2000; Brundrett, 2002). The change between saprotrophic and mycorrhizal lifestyles probably happened convergently, and perhaps many times, during the evolution of these fungal lineages (Hibbett et al., 2000). This may have facilitated the evolution of ectomycorrhizal lineages with a broad range of physiological and ecological functions that partly reflect the activities of their disparate saprotrophic ancestors. Although a few Basidiomycota clades are exclusively ectomycorrhizal (e.g., bolets), most clades comprise both ectomycorrhizal and saprotrophic species (e.g., Tricholomataceae), suggesting that the symbiotic ability involves a limited number of genes or key enzyme activities (Martin, 2007). The genome projects of several fungal species with distinct and varied lifestyles (i.e., saprobic, symbiotic, and parasitic strategies) will offer a great opportunity to reveal how evolution has played a crucial part in shaping fungal genomes to suit their own specialized lifestyles (Pain and Hertz-Fowler, 2008). In recent years, sequencing projects of ectomycorrhizal fungi have been launched, since they grow in pure culture and offer excellent opportunities for DNA investigation. Among the basidiomycetes, the genome of the ECM *Laccaria bicolor* has just been sequenced, providing new insights into the mutually beneficial relationship between the host and fungus (Martin et al., 2008a). The analysis of cell wall–degrading enzymes present in the genome has offered information on the adaptation capacity (Martin et al., 2008a; Martin and Nehls, 2009). As far as ascomycetes are concerned, *Tuber melanosporum* genome sequencing has been recently completed (http://mycor.nancy.inra.fr/; *Tuber* Genome Consortium, Martin et al., 2010), and it represents another opportunity to carry out a deeper investigation of the processes by which symbiotic organisms interact with plant roots in the ecosystem.

The use of DNA-based genotyping methods has recently modified our understanding of the specificity of mycorrhizal fungi toward their host plants. Most ECM fungi and plants are capable of association with multiple partners, although specialists occur in ECM symbiosis in both fungi and plants (e.g., Trappe, 1962; Molina and Trappe, 1982; Molina et al., 1992; Horton and Bruns, 1998; Horton et al., 1999; Cullings et al., 2000). For example, observations have shown that the host range of ericoid mycorrhizal fungi may also be extended to ectomycorrhizal plants in nature (Bergero et al., 2000; Vrålstad et al., 2000; Tedersoo et al., 2006) and, vice versa, typical ECMs like truffles or Russula have been detected in orchids (Girlanda et al., 2007; Selosse and Roy, 2009).

24.4.2.3 Other Mycorrhizal Fungi

Mycorrhizal fungi that associate with members of the Ericaceae and the related families include fungi that are all ascomycetes and generally do not form mycorrhizae with other vascular plants (Smith and Read, 2008). Studies on DNA sequences of fungi from these plants in Australia, Europe, and North America have revealed two or more distantly related groups of fungi involved in ericoid mycorrhizae (McLean et al., 1999; Monreal et al., 1999; Sharples et al., 2000). *Hymenoscyphus*-like fungi associate with Ericales and bryophytes throughout the world but other taxa are more restricted to specific geographic regions (Chambers et al., 1999; Read et al., 2000). It is not certain whether ericoid mycorrhizal fungi exist primarily as soil saprotrophs or as mycorrhizal associates of plants. If they are less dependent on plants than AM or ECM fungi, their capacity to form mycorrhizal associations would not be a driving factor in their evolution (Brundrett, 2002). Many ericaceous species colonize habitats where most of the nutrients in the soil are in organic form. It is widely accepted that the main benefit conferred to the ericaceous host plant by mycorrhizal infection is the enzymatic degradation of organic polymers in the soil and the transfer of some of the resulting products to the root (Perotto et al., 2002). Thanks to their mycorrhizal status, host plants can access otherwise unavailable organic N and P (Näsholm and Persson, 2001). In addition to nutritional benefits, there are other advantages that are likely to be of ecological significance. The ability of the fungal partner to sequester and, in some cases, to metabolize metal ions that are toxic to the plant appears to be important (Martino et al., 2003). This combination of nutritional and nonnutritional attributes of these associations contribute significantly to the ability of these plants to grow in contaminated soils as well as in natural habitats (Smith and Read, 2008).

Members of the Ericales species, with monotropoid or arbutoid mycorrhizae (ECM-like associations), generally have much higher host–fungus specificity than other ECM associations. The simultaneous formation of ectomycorrhiza in tree hosts and ectoendomycorrhiza in plants of the Arbutoideae and Monotropoideae subfamilies (family Ericaceae) has long been known (Girlanda et al., 2007). Orchids have mycorrhizal associations with soil fungi that are believed to be essential for seed germination and to assist the growth of adult plants (reviewed in

Waterman and Bidartondo, 2008). Most orchids have fairly specific fungal associates that vary according to the host species and habitat (Otero et al., 2002; Ma et al., 2003; Suarez et al., 2006). Most of these fungi are assigned to the anamorphic form genus *Rhizoctonia* (Roberts, 1999). Rhizoctonia-forming fungi constitute a polyphyletic group of fungi from three basidiomycetes families (Sebacinaceae, Ceratobasidiaceae, and Tulasnellaceae). It seems most likely that orchid fungi are a disparate group with many separate origins and the recruitment of new fungal lineages by orchids is an ongoing process. These fungi rarely fruit in an axenic culture, thus making their identification difficult when vegetative characteristics are used alone. The advent of molecular systematics has revolutionized the study of mycorrhizae as it allows direct identification without axenic isolation (Waterman and Bidartondo, 2008). The benefits provided by orchids to their mycorrhizal fungi, if any, are not clear, as these fungi seem to grow just as well without their hosts as they do with them. Several nongreen orchids (mycoheterotrophic) are known to rely solely on C from their mycorrhizal fungi (Selosse and Roy, 2009). In fact, green plants (mixotrophic) that can obtain additional carbon from their symbiotic fungi have also been discovered. Among them, orchids such as *Epipactis*, *Cephalanthera*, *Plantanthera*, and, more recently, some small green perennial shrubs of the Ericaceae family (referred to as pyroloids) have been shown to receive variable amounts of C from their mycorrhizal fungi (reviewed in Selosse and Roy, 2009). The mycorrhizal fungi that are associated with pyroloids and orchids belong to diverse fungal taxa (ascomycetes and basidiomycetes) that usually form ectomycorrhizal on tree roots. In some studies, it has been reported that these same fungi can be simultaneously detected as associated to the trees (Selosse et al., 2004; Julou et al., 2005). These data suggest that mixotrophic plants that live in forests derive photosynthates by sharing symbiotic fungi (Selosse and Roy, 2009).

24.4.3 Diversity in Mycorrhizal Features: Mycorrhizal Fungi Develop Structures Outside and Inside the Roots

According to their ability to colonize the root cells, mycorrhizal fungi are divided into two main categories: endo- and ectomycorrhizae. Since a detailed structural description of mycorrhizae is not the main aim of this chapter, we here only briefly review the main structural features that characterize mycorrhizal morphologies. More detailed information can be found in Peterson et al. (2004). Endomycorrhizal hyphae adopt a variety of colonization patterns during their penetration of host root cells. AM fungi depend on their hosts on a great extent and cannot survive for long without them. Once the fungus has overcome the epidermal layer, it develops an appressoria and grows inter- and intracellularly all along the root in order to spread fungal structures. During the symbiotic phase, some Glomeromycota (i.e., *Glomus* species) develop structures, called vesicles, that fill the cellular spaces, and probably act as storage pools. Only when the fungus has reached the cortical layers, does a peculiar

branching process start, which leads to highly branched arbuscules (Bonfante et al., 2009; Bonfante and Genre, 2010). These are the key structures that are produced during the symbioses, and are considered the site of nutrient exchange (Figure 24.8a). During endosymbiosis, regardless of the involved partners, a new apoplastic space, based on membrane proliferation, is built around all the intracellular hyphae (Bonfante, 2001). In AM, this new compartment is known as the interfacial compartment, and it consists of the invaginated membrane, the cell wall-like material, and the fungal wall, and plasma membrane (Balestrini and Bonfante, 2005). Colonization of the Ericales takes place via simple hyphal structures whose organization is not modified to any great extent during the presymbiotic and the intraradical symbiotic phases. Hyphae of ericoid fungi can form loops and bundles outside the host plants, appressoria and coils inside the epidermal root cells (Figure 24.8b). Basidiomycete fungi produce specialized coils (pelotons) in the orchid cells of the protocorm, which is the first developmental stage in orchids, as well as in roots and rhizomes (Figure 24.8c). The interface in both Ericales and orchid endomycorrhizae is morphologically similar to that of AM fungi but different in composition. This indicates that the invagination of the host membrane around the intracellular hyphae is a common biotrophic interaction, while the molecules that are detected at the interface depend to a great extent on the nutritional capabilities of the fungus and mirror its relationship with the host plant.

During the symbiotic phase, ectomycorrhizal fungi form a fungal sheath (the mantle), consisting of aggregated hyphae that surround the root surface. This mycelium is linked to extramatrical hyphae that explore the substrate and are responsible for the mineral nutrition and water uptake of the symbiotic tissues. From the inner zone of the mantle, some hyphae penetrate between the root cells to form the Hartig net (Figure 24.8d), an intercellular hyphal network inside the root tissues where metabolites are exchanged. The hyphae always remain apoplastic and can colonize epidermal and cortical cell layers (Barker et al., 1998). In ECM, plant and fungal cell walls are always in direct contact, forming the interface between the two partners; it has also been observed that the fungus can cause subtle changes in the host cell walls (Balestrini et al., 1996; Martin et al., 2007).

24.4.4 Nutrient Exchanges

The success of mycorrhizal fungi in time and space is mainly linked to the nutritional benefits they confer to their plant hosts: They take up phosphate (Pi) and other macronutrients as well as microelements and water from the soil and deliver them to the plant. The fungus, in turn, receives photosynthetic carbohydrates. The extraradical mycorrhizal mycelium (ERMM) captures water and nutrients from the soil and is an important sink for host carbon. Inside the roots, carbohydrates and mineral nutrients are then exchanged across the interface between the plant and the fungus (Smith and Smith, 1990). In recent years, several studies have been performed with the aim of investigating the transfer of nutrients between symbionts and, from the
FIGURE 24.8 Mycorrhizal features: (a), (b), (c) different endomycorrhizal associations and (d) ectomycorrhiza. (a) Arbuscular mycorrhiza (AM). Clover mycorrhizal root staining with cotton blue. Typical fungal structures are evident in the cortical layers: vesicles (V); arbuscule (A). The arrows indicate the intercellular hyphae. (b) Ericoid mycorrhiza. Confocal microscopic images of *Vaccinium myrtillus* roots colonized by *Oidiodendron maius* expressing enhanced green fluorescent protein (EGFP). Fluorescent fungal coils are visible in the root cells observed 1 year after fungal inoculation. Some mycorrhizal cells are clearly fluorescent whereas others fluoresce poorly, possibly due to a loss in viability of the fungal hyphae after prolonged infection. (c) Orchid mycorrhiza. Protocorm of *Serapias vomeracea* mycorrhized in vitro with *Tulasnella* spp. The asterisks indicate the region colonized by the fungus with the characteristic pelotons. S, region rich in starch. In the inset: higher magnification of colonized cells. P, peloton; CF, collapsed fungus; n, plant nucleus. (d) Transverse section of an ectomycorrhiza of *Tilia* sp. and *Tuber borchii*, showing the mantle (M) ensheathing the root and the Hartig net mycelium progressing among the host cells (arrows). (Images a, b, c, and d courtesy of Andrea Berruti, Elena Martino, Michele Rodda, and Mara Novero.)

literature, it seems clear that most of the information available is for AMs and ECM. For this reason, in this section, we will focus on these mycorrhizal categories.

24.4.4.1 Phosphate

Improved phosphate uptake is the main benefit for plants in AM symbiosis (Bucher, 2007; Javot et al., 2007). The extensive hyphal network of AM fungi influences the physicochemical properties of the soil and directly or indirectly contributes to the release of phosphate from inorganic complexes of low solubility (Parniske, 2008). The fungal phosphate transporters that are expressed in the extraradical mycelium are involved in the uptake of phosphate from the substrate. The characterization of a high-affinity Pi transporter (PT) in *Glomus versiforme*, which is expressed in extraradical hyphae (Harrison and van Buuren, 1995), was a milestone in the definition of AM fungi as biofertilizers. Detailed gene expression data have been obtained for the orthologous gene identified in *G. intraradices* (Maldonado-Mendoza et al., 2001) and another PT ortholog (*GmosPT*) has been described in *Glomus mosseae*, a particularly important AM fungus for natural and agricultural ecosystems (Benedetto et al., 2005). Current data suggest that Pi, taken up by the extraradical

mycelium from soil solutions, is translocated through the AM fungal hyphae as polyphosphate (poly-Pi). After hydrolysis in the arbuscule, the phosphorous is then released as Pi into the periarbuscular space (Javot et al., 2007). The subsequent import of Pi across the periarbuscular membrane into the plant cell is mediated by plant transporters. The study of plant PTs and of their functioning thus represents a key point to fully understand this process. Mycorrhiza-specific PTs, which are responsible for plant Pi uptake in arbuscule-containing cells, have recently been characterized in many plants: potato, tomato, rice, maize, barley, *Medicago truncatula*, and *Lotus japonicus* (Rausch et al., 2001; Harrison et al., 2002; Paszkowski et al., 2002; Glassop et al., 2005; Nagy et al., 2005; Guether et al., 2009a). Recent data, based on expression analysis of laser-dissected cells, have demonstrated that the five so far identified *LePT* genes in tomato (Nagy et al., 2005) are differentially expressed in cortical cell populations during the interaction with *G. mosseae* (Balestrini et al., 2007). All tomato PT genes are consistently expressed inside the arbusculated cells, suggesting that plants guarantee maximum Pi uptake through the activation of the whole gene family. On the fungal side, the presence of *GmosPT* transcripts in the arbusculated cells offers sound confirmation of the results

obtained by Benedetto et al. (2005) on the whole mycorrhizal root. The discovery that five plant genes and one fungal PT gene are consistently expressed in the arbusculated cells provides a new scenario for plant–fungus nutrient exchanges. The efflux of phosphate probably occurs in competition with its uptake and the fungus might exert control over the amount of phosphate delivered to the plant.

As far as ectomycorrhizal symbiosis is concerned, the host plants rely to a great extent on the fungus for Pi uptake. This might be due to the ability of ECM fungi to take up complex or immobilized forms of these nutrients that the root alone cannot absorb effectively. Phosphate in a soil solution is taken up by ECM hyphae and then translocated to the host roots, its absorption and efflux likely being regulated by intracellular Pi and inorganic polyphosphates (poly-Pi) pools. Although several low- and high-affinity PTs have been identified in the genome sequence of *L. bicolor* (Martin et al., 2008a) and other symbiotic fungi, the molecular processes controlling Pi uptake in ECM fungi still remain unknown. Among the 13 low- and high-affinity PTs of *Populus trichocarpa*, one is expressed specifically in endomycorrhiza, whereas another family member is preferentially expressed in ectomycorrhizal root tips (Martin, 2007). It might be possible that, in an analogous manner to the periarbuscular membrane localization of the PT in endomycorrhiza, another PT is localized in the plasma membrane of the host cortical cells in contact with the fungal Hartig net in ectomycorrhiza.

24.4.4.2 Nitrogen

In addition to their function in P nutrition, AM and, especially, ECM fungi play a pivotal role in the uptake of nitrogen (N) by plants. The results obtained over the last decade have provided support to the hypothesis (Read, 1991) that, at a global scale, mycorrhizal fungi may be making significant contributions to ecosystem nutrient cycling (Read and Perez-Moreno, 2003). Ectomycorrhizal fungi have biochemical and physiological attributes that make them highly efficient in scavenging organic N sources (Read et al., 2004). They may use soluble amino acids, and some of these fungi have highly developed proteolytic capabilities that enable them to directly access macromolecular N from the soil (Abuzinadah and Read, 1989). Functional complementation of a yeast strain deficient in amino acid transporters has led to the identification of amino acid transporters from *Amanita muscaria* (Nehls et al., 1999) and *Hebeloma cylindrosporum* (Chalot et al., 2002; Wipf et al., 2002), which seem to be involved in both the uptake of amino acids from the soil solution and the retention of amino acids under N-deprivation conditions. Evidence is now accruing that AM fungi may also have access to organic N sources (Hodge et al., 2001; Leigh et al., 2008), thanks to the expression of specific amino acid permeases (Cappellazzo et al., 2008). AM and ECM mycelia are also effective scavengers of either ammonium or nitrate, inorganic forms of N, and ECM mycelia are particularly effective in the uptake of ammonium. The molecular bases of nitrate and ammonium uptake have been investigated, and transporters as well as assimilating enzymes have been characterized in ECM

fungi such as *Pisolithus*, *Laccaria*, and *Tuber* (Jargeat et al., 2003; Javelle et al., 2003a, 2003b; Montanini et al., 2003, 2006). Ammonium absorbed by ERMM, or derived from nitrate reduction, may be rapidly assimilated into amino acids, mostly glutamine, and subsequently incorporated into mycelial proteins or translocated to the host; glutamine is also considered as the main translocation form in ECM mycelia (Martin and Botton, 1993). In *Tuber*, the glutamine synthase gene is highly expressed both during fruit body ripening (Lacourt et al., 2002) and N starvation (Montanini et al., 2003). Nitrate and high-affinity ammonium transporters are differentially expressed, at least 1.5-fold, in response to N deprivation (Montanini et al., 2006). Recent studies of ECM and AM mycorrhiza have highlighted the direct transfer potential of ammonia from fungal to plant cells at the symbiotic interface (Chalot et al., 2006). Together with the expression of putative ammonium exporter genes in the ectomycorrhizal fungus *A. muscaria*, expression analysis of a high-affinity ammonium importer from *Populus tremula-tremuloides* has revealed that its expression is root-specific, is affected by N nutrition, and strongly increases in a N-independent manner upon ectomycorrhiza formation, thus suggesting that ammonium could act as a direct N source, which is delivered by the fungus in ECM symbiosis (Selle et al., 2005). In AM fungi, elegant isotope-labeling experiments in combination with gene expression data (Govindarajulu et al., 2005) have demonstrated that inorganic N (nitrate and ammonium) is taken up by the extraradical mycelium, incorporated into amino acids, and translocated to the intraradical mycelium, mainly as arginine. Nitrogen is then transferred from the fungus to the plant as ammonium, without any loss of C skeleton, thanks to the catabolic arm of the urea cycle, which releases ammonium from arginine. This proposed mechanism requires that the enzymes for N assimilation are expressed differently in the extraradical and the intraradical mycelium. Transcripts encoding enzymes that assimilate inorganic N have in fact been detected in the extraradical mycelium, while those involved in arginine breakdown are located in the intraradical fungal structures (Govindarajulu et al., 2005; Lopez-Pedrosa et al., 2006). Furthermore, in agreement with the idea that NH_3/NH_4^+ is thought to be the preferential form of N released by the fungus and uptaken by the plant (Chalot et al., 2006), a mycorrhizal-specific *Lotus AMT* gene has recently been identified (Guether et al., 2009b).

24.4.4.3 Carbon

As obligate biotrophs, AM fungi receive all of their carbohydrates from the host plant. Many ECM fungi instead likely acquire carbon (C) both via host photosynthesis and assimilation following the degradation of soil C polymers, thus possibly reducing the amount of C needed from the host plant (Girlanda et al., 2007; Martin et al., 2007). In vivo NMR, coupled with ^{13}C labeling, and transcriptome profiling studies, are beginning to unravel some secrets of C transport processes at the molecular level in mycorrhizal symbioses (Pfeffer et al., 1999; Bago et al., 2000, 2002; Lammers et al., 2001; Nehls et al., 2001; Ferrol et al., 2002; Jakobsen et al., 2002; Simard et al., 2002). In both AM and

ECM mycorrhiza, sucrose, the primary transport carbohydrate in plants, can only be used as a C source by fungi if hydrolyzed by plant cell wall-bound invertases. Mycorrhizal fungi partly convert it into fungal storage metabolites (such as lipids, trehalose, and glycogen) and partly transfer it to the extraradical mycelium (Lammers et al., 2001; Nehls, 2008; Parniske, 2008). Fungal hexose transporters have been identified in ectomycorrhizal fungi and the fungal hexose uptake capacity is remarkably increased in the Hartig net hyphae of the model fungi *A. muscaria* and *L. bicolor*. It has also been suggested that the plant might be involved in the regulation of the carbohydrate drain toward the fungus. A poplar monosaccharide transporter gene has been shown to be upregulated in ECM (Grunze et al., 2004), suggesting that root cells can compete with fungal hyphae for the hexoses present in the apoplast of the Hartig net region (Nehls, 2008). Instead, no fungal hexose transporter-coding gene has so far been characterized in AM fungi. A member of a novel clade of hexose transporters has been identified in the symbiotic fungus *Geosiphon pyriformis*, which associates to cyanobacteria. Due to its phylogenetical position inside Glomeromycota and the capacity to establish endosymbiosis acting as a host, it has been suggested that a similar transporter might be expressed in arbuscules and localized in the fungal interface membrane in AM fungi (Schüßler et al., 2006). However, the relationship between *Geosiphon* (the fungal host) and the bacteria (the symbiont) is topologically reverse compared to usual AMs. However, mycoheterotrophic plants associate not only to orchid fungi (Selosse and Roy, 2009) but also with AM fungi, suggesting that the plants are likely to receive C from the fungus (Winther and Friedman, 2008). This would require AM fungi to have C transporters that work in the efflux direction. Recently, Cameron et al. (2008) have demonstrated a bidirectional C flux for an orchid–mycorrhizal symbiosis, although with a net plant-to-fungus C flux. In addition, due to the rapidity of the bidirectional flux, a dynamic transfer at an interfacial apoplast has been suggested instead of the reliance on the so far hypothesized digestion of fungal pelotons (Cameron et al., 2008).

In conclusion, although details of molecular mechanisms for mineral nutrients and C exchange between AM partners have emerged rapidly from genetic studies on nutrient transport and metabolic pathways, the full dissection of host–fungal interactions is still problematic. Consistent with their extensive genetic variability, mycorrhizal associations have different functional abilities and, therefore, offer distinct advantages to the host plant. Some mycorrhizal fungi are particularly effective in scavenging organic N, and are associated with plants for which the acquisition of N is crucial (Peter et al., 2001); others, instead, are more effective at P uptake and transport.

24.4.5 Perspectives

Mycorrhizal fungi also play an important role in nutrient cycles and in plant protection against pathogens and environmental stresses. It is therefore important to know and understand the role played by this important category of microorganisms. This can be obtained through the study of their biodiversity in land ecosystems and their role in ecological interactions, as well described in van der Heijden and Sanders (2002) and Finlay (2008). In spite of the enormous steps that have been made, thanks to molecular biology, the *databases* that gather the sequences of the fungal species, including mycorrhizal ones, are still not sufficiently developed to allow a complete analysis of soil communities. In order to overcome the limitations connected to the impossibility, in many cases, of growing fungi in cultures and also in order to obtain an overall vision of the fungal community, ecologists have begun to use an approach called environmental genomics or metagenomics (Chivian et al., 2008; Hugenholtz and Tyson, 2008). The term metagenomics refers to the idea that the total DNA extracted from an environmental sample represents the whole microorganism community and can be considered as a single genome (metagenome or megagenome). This approach promotes the study of communities of organisms found in nature without the cultivation and isolation of individual species. In this way, the majority of organisms existing in nature can be characterized. A further advancement in these studies is based on pyrosequencing, a new generation of high-throughput platforms. An approach based on 454 GS-FLX pyrosequencing has recently been used to analyze mycorrhizal communities in different soils in the Mediterranean and temperate forest environments (Buée et al., 2009; Öpik et al., 2009; Lumini et al., 2010). In future, investigations will take advantage of the new 454-FLX-titanium chemistry that allows longer read sequences to be obtained than with 454 GS-FLX. The Genome Sequencer (GS) FLX Titanium is an ultra high-throughput tool that can be used to generate 1 million sequencing readings with an average reading of about 500 nucleotides in a single operation run. This will allow detection of unknown mycorrhizal communities in molecular ecological researches and allow the dream of all soil microbiologists to be true, that is, of detecting all the fungi in a soil and of understanding their function.

25.1 Protozoa

Bryan Griffiths

Marianne Clarholm

Michael Bonkowski

25.1.1 Introduction

Protozoa belong to the "Protista," which is a paraphyletic group consisting of those eukaryotes that are not animals, true fungi, or green plants. The group is also defined on the basis of the absence of characters (i.e., no complex development from embryos, no extensive cell differentiation) and thus includes widely ranging microbes, including slime molds, algae, and protozoa (Clarholm et al., 2007). Protozoa in soil, which are active in water-filled pores and water films in larger pores, can be generally (or basically) classified in four groups: flagellates, ciliates, and naked and testate amoebae. Provided the appropriate sampling techniques are used, one can find protozoa in virtually every conceivable soil habitat. In harsh environments with low primary production, small forms with low nutrient demands normally dominate, whereas in richer environments their diversity, trophic complexity, and size tend to increase.

25.1.2 Background Biology

Flagellates are evolutionarily the oldest group. Those with one flagellum belong to the evolutionary lineage (unikonts) from which also amoebozoa, fungi, and animals are derived. Those with two (and more) flagella belong to a different evolutionary lineage (bikonts) from which, for example, plants are derived.

Most members of this group are small (4–15 μm body length). The smallest flagellates can squeeze through a 3 μm aperture, as a result of their flexible outer cell membrane.

Flagellates can swim by using up to eight flagella, which are long relative to the length of their body. Flagella may be used not only for swimming or anchoring but also to create a feeding current for catching bacterial cells. Although generally recognized as feeders of suspended bacteria, some important soil species (e.g., cercomonads) need to be surface associated to feed (Kiorboe et al., 2004).

Ciliates are evolutionarily the youngest group of protozoa, and in this group, we find the largest soil protozoa (20–600 μm body length). Ciliates have a more complicated structure than flagellates and have fur-like cilia that coat the whole body surface in distinct patterns that are used in classic taxonomy.

Amoebae have a polyphyletic origin and an uncertain evolutionary history. The general term amoeba, therefore, represents organisms with a similar type of organization of the cell, rather than a taxonomic unit or monophyletic group. Amoebae fall generally into two fundamental different taxonomic lineages: the Amoebozoa with broad pseudopodia and the Rhizaria with fine and slender pseudopodia (i.e., filopodia). Testate amoebae (Figure 25.1) have shells (tests), which are rigid constructions that can be proteinaceous, siliceous, or calcareous. The Arcellinida with broad pseudopodia and tests often composed of inorganic material bound into an organic matrix are generally larger (50–200 μm, and up to 300 μm) whereas the testate amoeba species with filopodia are generally smaller (10–100 μm). Testate amoebae usually have much longer generation times than naked amoebae. The body of the testate amoeba

always stays partly inside its test, whether in a resting cyst or in an active state. When moving around, the active individual stretches its pseudopodia out through the aperture to "walk" and feed on surfaces. Testate amoebae are found in substantial (approximately 30,000 g^{-1} dry wt) numbers in wet and acidic areas like bogs, mires, and the litter layers of coniferous forests. Possibly, the ecological niche for this group has been enlarged in eutrophied, acidified European forest soils, where the pH has decreased quickly with increasing air pollution. In these ecosystems, high numbers of testate amoebae are reported to have a significant impact when modeling nutrient turnover (Schröter et al., 2003). Naked amoebae are commonly 15–100 μm wide but only 1 μm thick when attached to a surface. Active individuals have a loosely shaped, jelly-lump-like body, which is strongly light quenching when observed in a light microscope. Members of this group generally have few characteristic morphological features seen by light microscopy. However, naked amoebae are not shapeless and their various morphotypes are used in classic taxonomy (Smirnov and Brown, 2004). An amoeba will move by changing its cytoplasm between a gel and sol form, "floating" along the surface or around a bacterial colony by pushing out pseudopodia in front while retracting pseudopodia behind it.

25.1.3 Distribution

Many surveys of protozoan morphospecies on a global scale have suggested a ubiquitous dispersal (Finlay, 2002), which would imply that global protozoan species richness would be relatively low, as the diversity of microbial species found in one

locality generally represents global levels of diversity within that habitat. An alternative moderate endemicity model (Foissner, 2006) suggests that some protozoan morphospecies have cosmopolitan distributions, while other protozoa have restricted distributions. A molecular screening study of cercomonads (heterotrophic flagellates, 5–50 μm long, among the most prominent bacterivorous protozoa) confirmed that (1) the diversity of 18S rDNA genotypes (18S types) within morphospecies can be very high, (2) many 18S types have cosmopolitan distributions, and (3) some 18S types within morphospecies have ecologically and/or geographically restricted distributions (Bass et al., 2007). That study also concluded that the number of protozoan species is hugely underestimated. Organisms with restricted distributions may prove to be important indicators of environmental change.

25.1.4 Feeding and Role in Food Webs

Most soil protozoa are bacterial feeders, collecting bacteria using some kind of catching device. This can be a flagellum (in the case of flagellates), an oral groove, or collar of specialized cilia in the ciliates and specific feeding cups in the amoebae. With food in ample supply, the bacterial remains will be excreted after only 30 min. This means that only the most palatable cytoplasmic parts of the bacteria will be used by the protozoa, while the remaining organic matter of good quality is delivered into the soil environment and to take part in the soil nutrient cycle (Griffiths, 1994). Flagellates, ciliates, and naked amoebae all have short generation times, in the order of hours, when food is amply available. Testate amoebae have longer generation times, where a doubling takes several days even with a good food supply (Clarholm et al., 2007).

Protozoa show feeding preferences, preferring bacteria without pigments, poisons, filaments, or external slimes; and, generally, Gram-negative bacteria are preferred to Gram-positive ones. To gain access to other food sources, unicellular yeasts and small fungal spores are phagocytized, while fungal hyphae, large fungal spores, and filamentous algae are enzymatically perforated by some amoebae and ciliates. Some ciliates attach a "feeding tube" to the hypha or spore to make a hole and to suck out the cytoplasm. Predatory protozoa can also feed on other protists and even nematodes, which are not always smaller than themselves.

In soil, protozoa are an important link in the food web (De Ruiter et al., 2002). By feeding on bacteria and, to a lesser extent, fungi, and then being consumed by larger fauna (e.g., individually by nematodes, mites, Collembola; and together with soil and organic matter by enchytraeids and earthworms), protozoa facilitate the flow of carbon and nutrients in the soil. The strength of a trophic interaction (i.e., the effects of the populations on each other) is important to the stability of the food web and interaction strengths for soil protozoa are particularly high (De Ruiter et al., 2002).

Modeling the soil food web can indicate what the most likely outcomes of various scenarios are, as has been applied to the effects of climate change and loss of biodiversity (Hunt and Wall, 2002). In their scenarios, increasing atmospheric CO_2 concentration (which was hypothesized to lead to plant N limitation) led to changes in the soil food web, including protozoa, which resulted in greater N mineralization and no N limitation. When the effects of deleting individual functional groups from the food web was modeled, the removal of amoebae led to a 60% decrease in omnivorous nematodes (a direct effect as they feed on amoebae) and 20%–30% increases in bacterial-feeding nematodes and predatory microarthropods (indirect effects as the nematodes no longer compete with amoebae for prey and the microarthropods feed on the nematodes). These results indicate the importance of compensatory mechanisms operating in the soil food web.

25.1.5 Methodology

All available evidence so far points at an uneven distribution of protozoa in space but also in time, with quickly vanishing "hot spots" of activity and long periods of inactivity as resting cysts. An adequate choice of sampling strategy is therefore crucial to any study and will be strongly dependent on the aim of the study. There is a high level of heterogeneity in most soils. For instance, when samples were taken only 5–10 mm apart from a single sample of sieved, mixed soil (experimentally as homogeneous as possible), amoebal numbers varied between 3000 and 5000 g⁻¹ and their Shannon diversity index varied from 1.8 to 2.6 (Anderson, 2002).

The most probable number (MPN) method is the only practical, quantitative technique available for microscopic organisms normally occurring in numbers of 10^3–10^4 g⁻¹ soil. These numbers are too low to lend protozoa to convenient direct counting. The MPN method has some disadvantages for protozoan enumeration, which may cause a bias in the counting (Adl, 2003). "Morphotype" approaches for the quantitative study of the diversity of flagellates and amoebae have been described (Ekelund et al., 2001; Smirnov and Brown, 2004). Some morphotypes represent taxonomically well-defined species, while others could include whole genera and so would require more detailed observations (i.e., by electron microscopy or sectioning) to differentiate the species. These practical approaches are clearly complementary to emerging molecular methods mentioned later.

Fatty acids can also serve as markers of protozoa. The signature fatty acid 20ω4 is routinely used to detect protozoa in aquatic environments, but since it can occur also in other eukaryotes, it is less easy to connect fatty acid 20ω4 to protozoa in soil, although there was a good correlation in a microcosm study on fresh manure added to an arable soil (Frostegård et al., 1997).

Regarding protozoan taxonomy, rapid progress in molecular methods is being made, and it is here that significant advances are expected. Despite some initial controversies, data from modern morphological approaches, biochemical pathways, and molecular phylogenetics are generally complementary (Adl et al., 2005). It is clear that the phylogenetics of protozoa are not straightforward. The traditional morphology-based classification grouped naked amoebae together in a macrotaxon named Sarcodina, molecular studies have now placed the majority of sarcodinids into two new supergroups: Amoebozoa and Rhizaria (Pawlowski and Burki, 2009). There is still a need to

generate taxon-rich multigene datasets to resolve their phylogenetic relationships and of environmental sequencing to increase taxon sampling in these supergroups. The diversity of 18S rDNA genotypes within traditional morphospecies can be very high, as mentioned above (Bass et al., 2007). Emerging, high-throughput sequencing technologies (pyrosequencing) of both DNA and RNA will, no doubt, reveal much more about the ecology of soil protozoa. Urich et al. (2008), for example, were able to demonstrate relative and quantitative abundances of RNA sequences from active protozoan groups in a grassland soil. Stable isotope probing (SIP), in which the microorganisms involved in the degradation of isotopically labeled substrates can be identified by separation of their isotopically labeled nucleic acids, can reveal the role of protozoa in specific food webs (Lueders et al., 2004).

So far, progress with the novel methods has been most rapid for individual taxa in aquatic environments (Caron et al., 2004), where protozoa can be concentrated by filtration. For example, real-time PCR has been carried out for the detection and quantification of the protozoan oyster parasite *Perkinsus marinus* in natural waters, and that technology is clearly applicable to also assess single species of interest in the soil environment. However, the low "carrying capacity" of soil for protozoa (typically 10^3–$10^4\,g^{-1}$) requires efficient extraction methods for subsequent analyses.

25.1.6 Ecological Roles for Protozoa in Soil

25.1.6.1 Shaping Microbial Community Structure

As a result of their feeding preferences and high consumption rates, protozoa have the capacity to strongly influence the bacterial species composition in soil. The presence of different amoebal and flagellate species resulted in the appearance of different bacterial communities (Rønn et al., 2002).

25.1.6.2 Protection and Distribution of Bacteria

Free-living naked soil amoebae, like *Acanthamoeba*, *Naegleria*, and *Hartmannella*, can act as reservoirs and modes of dispersal for human-pathogenic bacteria. Molecular methods have identified cells of the human pathogens: *Legionella*, *Chlamydia*, *Listeria*, and *Salmonella* inside the amoebae (Greub and Raoult, 2004; Brandl et al., 2005). At outdoor temperatures, the pathogens apparently live as endosymbionts, but at 30°C–37°C they change their lifestyle, becoming lytic and eradicating their hosts. Probably, the coevolution of bacteria inside amoebae has conditioned them to overcome the metazoan immune system, and made them capable of attacking human tissues. When the amoebae encyst, the pathogenic bacteria they harbor will be protected inside the cyst and be able to survive severe disinfection efforts. Although recognized so far as a long-term survival mechanism for pathogenic bacteria, this protection within a cyst should theoretically be operational with other soil bacteria.

25.1.6.3 Influencing Plant Growth

Previous reviews of the role of protozoa in the rhizosphere have tended to concentrate on their contribution to gross flows of carbon and nitrogen (Griffiths, 1994; Zwart et al., 1994) or their role in disease suppression (Curl and Harper, 1990). In the rhizosphere, bacteria are more important decomposer organisms than fungi, because of the large supply of easily decomposable organic matter (Wardle, 2002), so interactions between bacteria and their microfaunal grazers are of more consequence than those of fungi and their grazing animals. Microfaunal grazing in the rhizosphere is particularly important because plant available nutrients will be strongly sequestered during microbial growth (Kaye and Hart, 1997; Wang and Bakken, 1997) and would remain locked up in bacterial biomass if consumption by nematodes and protozoa would not constantly remobilize essential nutrients for plant uptake (Bonkowski et al., 2000). Recent reviews of the role of protozoa (Clarholm et al., 2007; Griffiths et al., 2007) have emphasized the importance of indirect interactions of microfaunal grazing. Protozoan grazing effects stimulating root growth by promoting specific rhizobacteria seem even more important than direct effects due to nutrient release (Bonkowski and Brandt, 2002) and is a development of the microbial-loop hypothesis as applied to the rhizosphere (Clarholm, 1985).

25.2 Nematodes

Robert McSorley

25.2.1 Introduction

Nematodes, or roundworms, which are common in most habitats, are a diverse group of invertebrates, including forms that inhabit marine, freshwater, or terrestrial habitats, as well as parasites of man and other vertebrates and of insects and other invertebrates. Many different kinds of nematodes inhabit soil, but while often present in large numbers, they often go unnoticed because of their cryptic habits and microscopic size, usually 0.5–2.0 mm in length. Some of the soil-inhabiting forms are plant parasites that are economically important in agriculture (Barker et al., 1998). Over 15,000 species of nematodes have been described (Poinar, 1983), but many more species remain unknown, and it is common to encounter undescribed species in most soil habitats.

25.2.2 Basic Taxonomy and Identification

Nematodes belong to the phylum Nematoda (Poinar, 1983), also referred to by some authors as the phylum Nemata (Thorne, 1961; Maggenti, 1991). Formerly, the Nematoda was considered a class within the phylum Aschelminthes, along with rotifers and related organisms (Barnes, 1965). The phylum Nematoda is divided into two classes: Adenophorea and Secernentea (Thorne, 1961; Poinar, 1983; Freckman and Baldwin, 1990). Poinar (1983) divides the two classes into 16 orders (Table 25.1). Some authors may recognize a slightly different arrangement, separating Triplonchida from Dorylaimida or Diplogasterida from Rhabditida (Andrassy, 1976; Maggenti, 1991; Lorenzen, 1994).

Some orders of nematodes are not common in soil, but certain stages of animal parasites may sometimes be found (Levine, 1968; Anderson, 1992) and marine nematodes may occur in soil

TABLE 25.1 Habitats and Taxonomic References for Nematode Orders, Based on Classification Scheme of Poinar (1983)

Order	Habitats[a]	References to Soil-Inhabiting Forms
Class Adenophorea		
Araeolaimida	Marine, freshwater, soil	Freckman and Baldwin (1990), Andrassy (1976), Ferris et al. (1973), Goodey and Goodey (1963)
Chromadorida	Marine, freshwater, soil	Freckman and Baldwin (1990), Ferris et al. (1973), Goodey and Goodey (1963)
Desmodorida	Marine, freshwater, soil	Freckman and Baldwin (1990), Ferris et al. (1973)
Desmoscolecida	Marine	
Dorylaimida	Soil, freshwater	Ferris (1971), Thorne (1974)
Enoplida	Marine, freshwater, soil	Freckman and Baldwin (1990), Andrassy (1976), Ferris et al. (1973), Goodey and Goodey (1963)
Mermithida	Invertebrates	
Monhysterida	Marine, freshwater, soil	Andrassy (1983)
Mononchida	Soil, freshwater	Jairajpuri and Khan (1982), Jensen and Mulvey (1968)
Class Secernentea		
Aphelenchida	Soil[b], invertebrates	Hunt (1993)
Ascaridida	Vertebrates, invertebrates	
Oxyurida	Invertebrates, vertebrates	
Rhabditida	Soil, freshwater, invertebrates, vertebrates	Andrassy (1983)
Spirurida	Vertebrates, invertebrates	
Strongylida	Vertebrates	
Tylenchida	Soil[b], invertebrates	Mai and Mullin (1996), Siddiqi (2000)

[a] Habitats listed in order of importance.
[b] Some soil-inhabiting forms also live in plant tissues.

from estuaries or other coastal habitats. Many nematodes are associates of insects (referred to as entomogenous nematodes), and are occasionally found in soil (Nickle, 1984; Gaugler and Kaya, 1990). These include insect-parasitic, or entomopathogenic, nematodes. The genera *Steinernema* and *Heterorhabditis* in the order Rhabditida have been used frequently in the biological control of soil insects (Gaugler and Kaya, 1990; Nguyen and Hunt, 2008). Plant-parasitic nematodes are common constituents of the soil fauna. Nonparasites of all types are referred to collectively as "free-living" nematodes.

Specific references are useful for the identification of some of the orders commonly occurring in soil (Table 25.1). More general texts (Thorne, 1961; Goodey and Goodey, 1963; Ferris, 1971; Andrassy, 1976; Freckman and Baldwin, 1990) include these as well as genera from orders that occur less frequently in soil.

In most texts, identification is to genus level; species identification is difficult (Barsi and Luca, 2008) and many species are undescribed.

25.2.3 Biology and Ecology

25.2.3.1 Morphology

Nematodes are unsegmented roundworms and most are worm-like in appearance, although some modifications exist. They have a complete digestive system, nervous, excretory, and reproductive systems, and longitudinal muscles, but lack respiratory and circulatory systems. Sexes are separate, although intersexes occur in some species (Wharton, 1986; Bird and Bird, 1991). Usually reproduction is sexual and amphimictic, although some species reproduce parthenogenetically or hermaphroditically (Poinar, 1983; Wharton, 1986; Bird and Bird, 1991). With substage lighting under a microscope, nematodes appear transparent, so that internal anatomical and morphological features important in taxonomy can be examined. The characteristics of the stoma (mouth region) and esophagus are particularly important in separating some of the nematode orders present in soil. In some groups, the stoma is modified into a needle-like stylet to aid in certain types of feeding.

25.2.3.2 Life Cycle

A typical nematode life cycle consists of the egg, four juvenile stages, and the adult (Wharton, 1986; Bird and Bird, 1991). The juvenile stages differ in size but are similar morphologically. Modifications and exceptions occur in some groups, such as the plant-parasitic genus *Meloidogyne*, in which later juvenile stages become swollen, developing into a saccate female (Poinar, 1983). The lengths of nematode life cycles vary from a few days to more than a year, with those of most common plant parasites averaging 3–6 weeks and those of some free-living forms only 1–2 weeks (Norton, 1978; Bird and Bird, 1991). In all cases, the duration of the life cycle is strongly dependent on temperature (Norton, 1978).

Various types of delayed development, such as the formation of dauer larvae, may occur in some species in response to adverse environmental conditions (Wharton, 1986; Bird and Bird, 1991). In extreme cases, nematodes of some species may enter anabiosis, an extended state of metabolic dormancy that may last for years (Norton, 1978; Wharton, 1986; McSorley, 2003). Anhydrobiosis is the anabiotic response to low soil moisture and desiccation (Wharton, 1986).

25.2.3.3 Nematodes in Belowground Food Webs

Nematodes are an integral part of food webs in soil ecosystems, appearing at several positions and levels due to their diverse feeding habits, which form the basis for subdivisions into a number of trophic groups (Elliott et al., 1988; Moore and de Ruiter, 1991; Yeates et al., 1993). Five of these groups are frequent in soil (Table 25.2): bacterivores feed on soil bacteria; fungivores feed on fungal mycelia; herbivores, or phytophages,

TABLE 25.2 Feeding Habits of Nematodes Found in Soil Ecosystems

Order	Bacterivores	Fungivores	Herbivores	Omnivores	Predators
Class Adenophorea					
Araeolaimida	All soil forms				
Chromadorida[a]	Few				
Desmodorida	Some				
Dorylaimida		Some	Some	Some	Some
Enoplida	Some			Few	Some
Monhysterida	Most soil forms				
Mononchida	Few				Most
Class Secernentea					
Aphelenchida[b]		Many	Some		Few
Rhabditida[b]	Most				Some
Tylenchida[b]		Some	Most		

   [a] Mostly algivores.

   [b] Some members in these orders are insect parasites or insect associates.

are the plant parasites; predators feed on nematodes and other small invertebrates; omnivores feed on a variety of foods such as fungi, algae, small invertebrates, bacteria, etc. (Freckman, 1982; Freckman and Baldwin, 1990). Feeding habits vary within the nematode orders occurring in soil. Because the biology of many nematodes is relatively unstudied, the food habits of some groups are unknown (Yeates et al., 1993). Some of these groups, such as the family Tylenchidae in the order Tylenchida, which are common in soil, are sometimes grouped as "plant associates" since feeding habits remain unclear. Recent work has clarified that several species of *Filenchus*, an abundant genus in this family, feed as fungivores (Okada et al., 2005).

25.2.3.4 Abundance, Distribution, and Diversity

A diverse nematode fauna of typically two or three dozen different genera are present in most soils, with numbers in the range of 10^6–10^7 m^{-2}, as illustrated by results from selected earlier studies (Table 25.3). Subsequent studies typically report 20–40 genera per terrestrial site, with a trend toward greater diversity and numbers of taxa under organic versus conventional management (Yeates and Boag, 2003). Grasslands may show unusually high nematode abundance, with numbers in excess of 10^7 m^{-2} reported in several cases (de Goede and Bongers, 1998). When dry biomass is reported, values in the range of 100–200 mg m^{-2} are common (Sohlenius, 1980) but can be greater in communities containing a high percentage of large dorylaimid omnivores (Wasilewska, 1971; Ferris and Ferris, 1974). The percent composition of the nematode fauna by trophic group varies, depending on the plant species present and the geographic location. Relatively wide ranges in trophic composition or abundance within a site may result from seasonal variation. Enrichment with organic matter stimulates the entire soil food web, increasing both nematode numbers and the variety of taxa present (Ferris et al., 2004; Wang et al., 2004; Ferris and Bongers, 2006). Conversely, nematode abundance may be decreased in polluted sites (Ekschmitt and Korthals, 2006) or in sites disturbed due to

land management (Todd et al., 2006) or some types of agricultural practices (Berkelmans et al., 2003; Yeates and Boag, 2003; Wang et al., 2006).

25.2.4 Importance to Soil Processes

25.2.4.1 Decomposition and Nutrient Cycling

Sohlenius (1980) reviewed the allocation of energy for production or respiration in nematode communities at various sites. Roughly 2/3 of the energy assimilated by nematodes was liberated as respiration energy, with the remainder used for production (Sohlenius, 1980). This energy stored within nematode tissues is then available for cycling to organisms that feed on nematodes. The role of nematodes in energy cycling and flow is significant because their consumption and population turnover rates are high. Estimates of nematode consumption of root biomass from several studies in Colorado and South Dakota prairies ranged from 34.8 to 57 g m^{-2} (more than vertebrate herbivores) and in one study amounted to 5.8%–12.6% of annual net primary production (Ingham and Detling, 1984).

Nematodes occupy several key positions in soil food webs (Moore and de Ruiter, 1991). Since herbivores and microbivores (bacterivores plus fungivores) make up the most abundant nematode groups in most systems, energy flow through the soil nematode community takes two major pathways. Nematode herbivores function only as primary consumers, removing energy directly from plant roots, whereas energy flow from plant to bacterivores or fungivores is indirect. Nematodes do not feed directly on organic matter of plant origin but on the bacteria and fungi that break down this material. Other less abundant nematode groups function as predators that feed on nematodes and other small invertebrates, or as omnivores that feed both as predators and as bacterivores or fungivores. In one study, 34%–44% of the energy in organic matter from crop residues that was passed through bacteria and fungi was eventually consumed by nematodes within a year (Wasilewska and Bienkowski, 1985). Changes in the relative

[a] Mean or range reported, depending on study.

proportions of nematode bacterivores and fungivores over time reflect changes in the pathway of decomposition (Wasilewska and Bienkowski, 1985). Nematodes accelerate the decomposition process by dispersing relatively immobile microflora to new sites and by their feeding, which regulates bacterial growth and decomposition rates (Ingham et al., 1985; Wasilewska and Bienkowski, 1985; Freckman, 1988). Overgrazing of bacteria is avoided as nematodes in turn are regulated by mites and other invertebrate predators (Whitford et al., 1982; Elliott et al., 1988).

The increased decomposition rates resulting from nematode feeding increase the recycling and mineralization of C and other elements (Ingham et al., 1985; Freckman, 1988). Nematodes are particularly important in recycling N, which can become immobilized in bacterial populations during decomposition (Freckman,

1988). Since nematodes have a higher C:N ratio (8:1 to 12:1) than their bacterial food source (3:1 to 4:1) (Wasilewska and Bienkowski, 1985), their feeding results in the excretion of N, mostly as NH_3 (Freckman, 1988). Numerous studies confirm the increase of NH_4^+ and other inorganic N sources in soil with nematodes present, and increased N levels in plant tissue have resulted in some instances (Ingham et al., 1985; Freckman, 1988). Nematodes are also important in the enhanced mineralization of P (Ingham et al., 1985; Freckman, 1988), and even S in some instances (Freckman, 1988).

25.2.4.2 Economic Importance to Agriculture

Nematode herbivores are of particular importance in agriculture because of their potential to damage the roots of crop plants (Norton, 1978). Ectoparasites feed at the root surface but do not enter roots, while endoparasites may feed and live within root tissue. Feeding by large numbers of plant-parasitic nematodes can result in yield losses, wilting, nutrient deficiency symptoms, and other problems associated with a damaged root system. Nematode problems of various crops are already reviewed (Nickle, 1984; Luc et al., 1990; Evans et al., 1993; Barker et al., 1998; Chen et al., 2003); some of the most important nematode pathogens of crops are shown in Table 25.4.

TABLE 25.4 Major Nematode Pathogens of Selected Agricultural Crops

Crop	Nematodes
Alfalfa (*Medicago sativa*)	*Ditylenchus dipsaci, Meloidogyne* spp.
Banana (*Musa* spp.)	*Radopholus similis, Helicotylenchus multicinctus*
Citrus (*Citrus* spp.)	*Tylenchulus semipenetrans, R. similes*
Coconut (*Cocos nucifera*)	*Bursaphelenchus (Rhadinaphelenchus) cocophilus*
Coffee (*Coffea arabica*)	*Meloidogyne* spp., *Pratylenchus* spp.
Cotton (*Gossypium hirsutum*)	*Meloidogyne incognita, Rotylenchulus reniformis*
Grape (*Vitis vinifera*)	*Meloidogyne* spp., *Xiphinema* spp.
Maize (*Zea mays*)	*Pratylenchus* spp., *Belonolaimus longicaudatus*
Peanut (*Arachis hypogaea*)	*Meloidogyne* spp., *Pratylenchus brachyurus*
Pine (*Pinus* spp.)	*Bursaphelenchus xylophilus*
Potato (*Solanum tuberosum*)	*Globodera* spp., *Meloidogyne* spp., *Pratylenchus* spp.
Rice (*Oryza sativa*)	*Hirschmanniella* spp., *Aphelenchoides besseyi*
Soybean (*Glycine max*)	*Heterodera glycines, Meloidogyne* spp.
Sugar beet (*Beta vulgaris*)	*Heterodera schachtii, Meloidogyne* spp.
Sugarcane (*Saccharum* spp.)	*Pratylenchus* spp.
Sweet potato (*Ipomoea batatas*)	*Meloidogyne* spp., *R. reniformis*
Vegetables	
Family: Cruciferae (cabbages, etc.)	*H. schachtii, Meloidogyne* spp.
Family: Leguminosae (beans, peas)[a]	*Meloidogyne* spp., *R. reniformis, Heterodera* spp.
Family: Solanaceae (tomatoes, etc.)[a]	*Meloidogyne* spp.
Wheat (*Triticum aestivum*)	*Heterodera avenae*

25.2.5 Methods

25.2.5.1 Collection, Sampling, and Extraction of Nematodes

Methods for collection of samples and extraction are listed in Table 25.5. The irregular horizontal spatial distribution of nematodes presents particular problems in obtaining precise samples from the field (Barker and Nusbaum, 1971; Barker and Campbell, 1981; Goodell and Ferris, 1981; Goodell, 1982; McSorley, 1987). Therefore, soil cores are typically collected from a number of points within the field and then combined to make a composite sample. The sampling plan is the number of cores needed to form the sample, for example, 20 cores per 1.6 ha in North Carolina (Barker and Nusbaum, 1971; Barker and Campbell, 1981). Some methods for extraction of nematodes from soil depend on nematode activity (active techniques) while others can be used to extract inactive or dead nematodes (passive techniques) (Table 25.5). Since many different methods are used for extracting

nematodes from samples, comparison of counts between laboratories can be difficult and should be standardized (McSorley, 1987). Multiple methods may be needed for efficient extraction of nematode communities (McSorley and Frederick, 2004).

25.2.5.2 Community Structure Analysis and Bioindicators

Data on the population density of a key genus or species are often collected in nematology. Studies have been conducted to assess community structure rather than individual taxa (Table 25.5). Nematode succession and increasing numbers of taxa result as plant communities become more complex or as soil food webs are enriched (Niles and Freckman, 1998; Wang et al., 2004). In the development of the maturity index, Bongers (1990) classified nematodes into five successional classes (cp scale), ranging from families that showed characteristics of good colonizers (cp-1) to those best adapted as persisters (cp-5). These successional classes

TABLE 25.5 Outline of Methods for Sampling and Extraction of Nematodes from Soil and Roots

Procedures	References
Collection of Samples	
Field collection	Barker and Nusbaum (1971), Barker and Campbell (1981), Goodell (1982), McSorley (1987), Freckman and Baldwin (1990)

Community structure indices	Bostrom and Sohlenius (1986), Bongers (1990), Freckman and Ettema (1993), McSorley (1993), Wasilewska (1994), Neher and Campbell (1994), Yeates (1994), McSorley and Frederick (1996), Bongers and Bongers (1998), Neher (1999), Yeates and Bongers (1999), Ferris et al. (2001)

(cp scale) were coupled with nematode feeding groups (bacterivores, fungivores, etc.) to create a matrix that defined nematode guilds (Bongers and Bongers, 1998; Ferris et al., 2001). Analyses based on nematode guilds have been useful in understanding and interpreting the condition of soil food webs (Ferris et al., 2001; Ferris and Matute, 2003; Ferris and Bongers, 2006).

Environmental changes impact both nematode numbers and community structure (Freckman and Ettema, 1993). The ability of nematodes to respond to changes, as well as their diversity, widespread distribution, size, abundance, and other features make nematodes useful as bioindicators of ecological disturbances (Freckman, 1988; Bongers, 1990; Freckman and Ettema, 1993; Neher and Campbell, 1994). Much work has focused on the utility of various indices of community structure for this purpose (Freckman and Ettema, 1993; Neher and Campbell, 1994; Wasilewska, 1994; Yeates and Bird, 1994; McSorley and Frederick, 1996; Ferris and Matute, 2003; Ferris and Bongers, 2006). Nematodes are particularly useful as bioindicators of organic enrichment and condition of soil food webs (Ferris et al., 2001; Ferris and Bongers, 2006). They have potential as bioindicators of pollution from heavy metals (Ekschmitt and Korthals, 2006), and possibly as bioindicators of historical changes and alterations in land use (Todd et al., 2006).

As global climate changes, geographic distributions of plant-parasitic nematodes could slowly expand into cooler areas when temperatures increase. Yeates and Boag (2003) speculate that plant-parasitic nematodes and their hosts would likely migrate together. Increasing soil temperature affected the nematode community, resulting in shifts to higher percentages of fungivorous and plant-parasitic genera (Ruess et al., 1999). Because the nematode life cycle is temperature-dependent, life cycles would become more rapid, possibly resulting in an extra generation per year in some cases. If agriculture expands into regions that now have short growing seasons, it is likely that the plant-parasitic nematode problems typical of those crops will follow.

25.3 Microarthropods

Mark G. St. John

D.A. Crossley, Jr.

David C. Coleman

25.3.1 Introduction

Microarthropods are a major fraction of the soil mesofauna, namely, those arthropods with body widths ranging between approximately 0.05 and 2 mm and body lengths between 0.1 and 10 mm (Figure 25.2). This scheme of classification, although imprecise, is practical, defined by the method of sampling. Microarthropods are sampled by collecting a fragment of habitat (e.g., a soil core) and extracting them from it, while macroarthropods (Section 25.4) are usually hand-collected or trapped. Microarthropods are dominated by two groups: springtails (Collembola, a group of near-insect hexapods) and mites (Acari, a subclass of arachnids).
FIGURE 25.2 A generalized classification of soil fauna by body length. Microfauna, mesofauna, and macrofauna plotted on a body length scale from 0.02 to 83.2 mm. (From Wallwork, J.A. 1970. Ecology of soil animals. McGraw Hill, New York.)
FIGURE 25.3 Mite (gray boxes, solid whiskers) and collembolan (white boxes, dashed whiskers) population densities in eight biomes. The desert biome includes both hot and cold (Arctic and Antarctic) systems. Data are presented as median lines boxed by the interquartile range with the most extreme values as whiskers. (Data from Petersen, H., and M. Luxton. 1982. A comparative analysis of soil fauna populations and their role in decomposition processes. Oikos 39:287–388.)

Together, springtails and mites account for about 90% of the microarthropods in most soil systems. The remaining 10% of soil microarthropods often include Diplura, Protura, Symphyla, Pauropoda, Pseudoscorpiones, fly (Diptera) larvae, thrips (Thysanoptera), and some small spiders (Araneae), true bugs (Hemiptera), and beetles (Coleoptera). Immature stages of many insect orders are collected from soil samples, and some may be considered microarthropods for purposes of a particular study.

Microarthropods are found wherever there is soil, from the Arctic to the tropics to the Antarctic. Densities range widely, with numbers of individuals over 100,000 m^{-2} being typical (Figure 25.3). The assemblage and abundances of species at any one location will be highly dependent on season and depth of sampling. Many studies only consider fauna in the top 5 or 10 cm of soil and assume >80% of the total population is found there; however, microarthropods often migrate to below 10 cm when soils become dry and in desert systems (Petersen and Luxton, 1982). Forested systems generally support higher microarthropod population densities than do grasslands and savannas, deserts, or agricultural systems. Densities tend to be highest in boreal forests (Taiga, temperate coniferous), followed by temperate forests (deciduous, hardwood and mixed) and finally tropical forests. Species richness of microarthropods follows almost the opposite trend, with lower richness at high latitudes than either warm temperate or tropical regions (Maraun et al., 2007). Soils in agroecosystems may have sparse populations, although microarthropod abundance increases under conservation tillage management (Hendrix et al., 1986).

Together with protozoans, nematodes, and other small soil fauna, microarthropods make up a food web of several trophic levels. Their net ecological effects include the breakdown of organic matter and mobilizing nutrient elements. Despite the relatively small biomass of microarthropods in the soil—as little as 10% of the energy flowing through a soil system is assimilated by microarthropods—their indirect action can have large effects (both positive and negative) through control of bacterial and fungal populations (Macfadyen, 1963; Hunt et al., 1987; Huhta, 2007). These influences are strongest in warm temperate and tropical regions (Wall et al., 2008). Microarthropods are also important drivers of soil formation and maintenance, converting plant residues into fine microstructures with their activities and feces (Rusek, 1986). A lesser appreciated role for soil microarthropods is as an essential resource for aboveground predators (Scheu, 2001; Saporito et al., 2007).

Much of our current understanding of the abundance, diversity, and functioning of soil microarthropods (in addition to soil fauna in general) has built on a foundation of work from the International Biological Program (1960s–1970s); a comprehensive resource summarizing this work can be found in Petersen and Luxton (1982). Huhta's (2007) and Coleman's (2008) historical accounts of soil ecological research also provide many essential microarthropod references.

25.3.2 Biology and Ecology

25.3.2.1 Collembola

These minute hexapods are commonly called springtails in reference to an abdominal appendage, the furcula, which enables many species to leap through the air (Figure 25.4). They possess a characteristic ventral tube (collophore, from which their name is derived) with eversible sacs, important in moisture balance. Their mouthparts are internalized like those of the also-wingless Diplura and Protura, collectively earning them the artificial grouping "entognathous hexapods." Arrangement of these groups with the subphylum Hexapoda is still unresolved; however, it is now widely accepted that none of the entognathous hexapods belong to the class Insecta as some authors once believed.

Collembolan numbers in terrestrial ecosystems range between 10^4 and 10^5 m^{-2} and typically constitute 20%–50% of soil microarthropod populations. They are opportunistic species and dominate microarthropod communities where resources are abundant. Some species may be observed as obvious swarms on soil or snow surfaces during population blooms, earning them the name "snowfleas." Their habitat extends from the litter layers of soil down into deeper substrata. Collembolan morphology reflects their habitat in that surface dwellers are larger, often colored, with well-developed furcula and long antennae, while those inhabiting the soil are white, with reduced furcula and shorter antennae (Figure 25.4).

Although most collembolans are fungivores or saprovores, a few species are economic pests, and some have proved to be predaceous. Like other microarthropods, collembolans may feed opportunistically upon nematodes or other periodically abundant resources in the soil. Collembolans appear to be attracted to plant roots and may be important in rhizosphere dynamics. In experiments,

FIGURE 25.5 Scanning electron micrograph of an oribatid mite (*Punctoribates palustris*). (Courtesy of Valerie Behan-Pelletier, Agriculture and Agri-Food Canada.)

FIGURE 25.4 Collembolan life forms. (Syncroscopy images courtesy of Ian Hogg, University of Waikato.)

collembolans grazed selectively on fungal root pathogens, thereby protecting cotton plants (Curl and Truelove, 1986).

For further information, Hopkin (1997) provides an introduction to the Collembola. For more depth, Deharveng (2004) is an excellent resource for both classical and recent collembolan reference works. Additionally, several Internet resources maintained by world authorities are currently available, easily found, and should be consulted for up-to-date information on collembolan literature, biology, and systematics.

25.3.2.2 Soil Mites (Acari or Acarina)

Mites are the second most diverse group of animals on earth, next only to insects, and the vast majority of species live in soil (Figure 25.5). Being members of the class Arachnida, mites are eight-legged, chelicerate relatives of spiders and scorpions. Unlike the typically predatory nature of arachnids, mites have diversified into all manner of additional feeding strategies including plant feeders, parasites, parasitoids, detritivores, fungivores, and scavengers. Mite bodies are unsegmented; however, secondary sutures of their bodies can roughly approximate the separation of tagma (e.g., head, thorax, abdomen, cephalothorax) as found in other arthropods.

Traditionally four suborders of soil mites were recognized (common alternative names are in parentheses): Astigmata (Acaridida), Mesostigmata (Gamasida), Oribatida (Cryptostigmata, Oribatei), and the Prostigmata (Actinedida). Most published works on soil mites subscribed to this taxonomic system; however, decades of investigation (O'Connor, 1984; Norton et al., 1993) have culminated in a new arrangement (Krantz and Walter, 2009). Astigmata is now recognized as a highly derived cohort (Astigmatina) within the Oribatida—but they are so distinct in terms of biology and morphology that it is sensible to continue treating them as separate groups. Mesostigmata has been elevated to the level of order with little change while some members of the Prostigmata have been moved into the new suborders Sphaerolichida (order Trombidiformes) and Endeostigmata (order Sarcoptiformes). These six mite groups are considered in the following sections using the most current systematic understanding, in a manner that allows reconciliation of data reported under past taxonomic schemes.

Each of these groups (as well as mite groups not typically found in soil) is covered in more depth, with illustrated keys to families of the world in relevant chapters of Krantz and Walter (2009). Also see Evans (1992) and Walter and Proctor (1999) for more information on the biology and ecology of mites. For more in-depth coverage, it is recommended to attend the soil mites component of the Acarology Summer Program held at The Ohio State University, Columbus, Ohio. Understanding of this group is in rapid flux and the most current information and materials are disseminated by world experts here, biannually.

25.3.2.2.1 Order Mesostigmata (Parasitiformes)

Mesostigmata are generally flattened, tick-like mites. Although not as numerous as other mite groups, mesostigmatids are

important predators in soil systems, particularly on nematodes and other arthropods. They range in length from 0.2 to 3 mm. Smaller species are mainly nematophagous. Larger ones are active predators of collembolans, small arthropods, and their eggs. A few species within the Uropodina, Digamasellidae, and Ascidae are atypically fungivore–saprovores. In forest floors, litter species tend to be larger and well armored (sclerotized), and mineral soil inhabitants are generally smaller, softer, and colorless. In agricultural soils, Mesostigmata are attracted to decomposing roots. Mesostigmatids are also championed as useful bioindicators in a variety of systems (Beaulieu and Weeks, 2007, and references therein) because of their predatory role and *r*-strategist lifestyle. At least one species, *Geolaelaps* (*Hypoaspis*) *aculeifer*, is a standard organism in ecotoxicological tests.

A large and comprehensive, international literature discusses soil mesostigmatid mites but the group is in need of a comprehensive revision. Useful references include Evans and Till (1979), Krantz and Ainscough (1990), and Karg (1993).

25.3.2.2.2 Suborder Prostigmata (Acariformes: Trombidiformes)

Representatives of this very diverse suborder are often among the most numerous of the soil mites. In general, they are delicate, white to colorless, and subject to desiccation. However, any brightly colored mites encountered are almost certain to be prostigmatids as well. They range widely in size from about 0.1 to several millimeters in length.

Functional generalizations about the Prostigmata are difficult. While many soil-dwelling species are predaceous, some are fungivorous and these species may become abundant in decomposing organic litter. Many Prostigmata are opportunistic species, able to reproduce rapidly when food resources become abundant. Large populations may build in disturbed situations, such as forest clearings, drained marshes, and so forth. Larger Prostigmata are predators of other arthropods, including the bright red velvet mites seen walking on the soil surface in the spring, or following rains in desert systems. Smaller species with piercing stylet chelicerae are generally fungal feeders in soil and litter layers, but some are effective predators on small arthropods or nematodes. Some species may switch between fungal hyphae and nematodes, or perhaps supplement a fungal diet with occasional protein. Additionally, phytophagous species are frequently recovered in soil samples, further weakening generalizations about this suborder. However, prostigmatid behaviors are relatively stable, and morphologies distinct, at the family level. Identification of prostigmatid families (or further) is profitable, if not prudent, in ecological studies where they are abundant.

Kethley (1990) provides a comprehensive treatment of the Prostigmata. He gives extensive tables of abundance and biomass for the Prostigmata in a range of habitats, as well as a key to families commonly found in soil.

25.3.2.2.3 Suborder Sphaerolichida (Acariformes: Trombidiformes)

This suborder is composed of only two monogeneric families: Sphaerolichidae (*Sphaerolichus*) and Lordalycidae (*Hybalicus*).

Sphaerolichida tend to be small, pink, globular mites resembling species of Endeostigmata, of which they were traditionally considered to be members. While of cosmopolitan distribution, species of Sphaerolichida are rarely encountered in great numbers and they have received little study. There is evidence of particulate fungal-feeding in species of both genera although species of *Sphaerolichus* are more likely to be ambush predators.

25.3.2.2.4 Suborder Endeostigmata (Acariformes: Sarcoptiformes)

There are currently 10 recognized families of Endeostigmata, which have been treated as Prostigmata by some authors. They are mostly small (0.2–1.0 mm), globular to cylindrical, pale white to pink, and weakly armored mites, often with highly modified setae (hairs) and/or patterned cuticles; but nematode wormlike forms specializing in deep-soil habitats can also be found. Many appear to be detritivores or omnivores, some have piercing mouthparts, which would suggest fungal-feeding, while others are assumed predaceous on nematodes.

25.3.2.2.5 Suborder Oribatida (Acariformes: Sarcoptiformes), Exclusive of Astigmatina

Oribatid mites (Figure 25.5) are often the most numerous of microarthropods in soils. Most adult oribatids range from 0.2 to 0.7 mm in length, are often brown and beetle-like in form (sometimes called beetle, armored, or moss mites). The armored appearance of adults is usually from sclerotization (and melanization) of adult exoskeletons although some species harden their integuments with Ca deposits (e.g., $CaCO_3$), evidently accumulated from their fungal food sources. Together with snails, millipedes, and isopods, oribatids may play a significant role in Ca metabolism in soil systems. The immature stages of many oribatid mites are typically weakly sclerotized (sometimes being mistaken for Prostigmata or Endeostigmata) and do not resemble adults to the extent that recognition of species based on immatures is often impossible.

Densities of oribatid mites in soils, as with Collembola, typically range from 10^4 to 10^5 m^{-2}. In deciduous forests, peaks of abundance occur in autumn and spring, with numbers remaining high during summer months. Year-to-year variation may be large, but fluctuations are not as wide as with Collembola. Coniferous forest (boreal/Taiga) floors typically support the largest populations of oribatids, followed by temperate deciduous hardwood forest, grasslands/savanna, and tundra. Any disturbance of soil (e.g., cultivation of agricultural soils, introduction of bioturbators) typically reduces oribatid population sizes (Maraun et al., 2003).

Oribatids are similar to Collembola in being primarily particulate-feeding fungivores and saprophages that may ingest nematodes opportunistically; however, their rates of respiration and reproduction are much lower than collembolans. Oribatids maintain similarly high populations by longer survivorship. As a group they are often considered to be generalist feeders, but individual species are quite specific in what they consume (Schneider and Maraun, 2005) and immatures may

feed on different resources than adults (Siepel, 1990). Oribatids are important drivers of decomposition and soil formation. They are able to break down organic litter by fragmenting or tunneling within materials such as leaves and stems with their stout chelate chelicerae while creating fine soil microstructure with their feces. Their activities may stimulate microbial immobilization of nutrient elements, but at the same time, ingestion of fungal hyphae may destroy hyphal bridges (Lussenhop, 1992).

There are approximately 10–100 times more asexual species within the oribatids than is typical for other animals. Asexuality evolved multiple times within Oribatida, in ancient clades, with sexuality re-evolving in some taxa (Domes et al., 2007).

Oribatid mites are often the focus of soil biodiversity studies or used in bioindication (Behan-Pelletier, 1999) because they have a high local (alpha) diversity (an organic temperate forest soil will have upward of 100 species); are found wherever there is soil; are relatively well documented; and their *K*-strategist life history makes them sensitive indicators of soil disturbance and rehabilitation (St. John et al., 2002). The diversity of oribatids is a function of microhabitats, not abundance (Aoki, 1967; Osler and Beattie, 1999; Hansen, 2000). There are over 9000 described species of oribatid mites (Schatz, 2002), which is estimated to be only 20% of the actual world fauna (Behan-Pelletier and Bissett, 1992). The identification of oribatids to genus has been greatly facilitated by Janos Balogh, who has authored a series of well-illustrated works (Balogh and Balogh, 1992).

25.3.2.2.6 *Cohort Astigmatina (Acariformes: Sarcoptiformes: Oribatida)*

This diverse group of mites contains pests of stored products (commonly called cheese mites), and vertebrate commensals and parasites; however, soil-dwelling astigmatids are typically saprophagous or fungivorous. Soil astigmatids are pale white, soft, globular to cylindrical mites ranging approximately 0.2–1.8 mm in length often with prominent, long setae. Immature stages modified for dispersal (hypopus, *pl.* hypopi) are somewhat lens-like in shape (bearing a passing resemblance to mites in prostigmatid family Scutacaridae) with a prominent set of "suckers" on their venter used for affixing themselves to other arthropods (phoresy). Astigmatid adults and immatures are only occasionally found in soil samples but can appear in great numbers under favorable conditions due to their extreme *r*-strategist nature. These mites seem to be associated with highly organic, decomposing materials such as manure. Buried agricultural residues may support astigmatid blooms, and they can become pests of root crops on occasion.

25.3.3 Sampling and Analysis

Microarthropods are not sampled directly; rather, samples of habitat—typically cores 5 cm diameter × 5 cm deep—are collected and microarthropods are extracted from them (Figure 25.6). Extraction can be either "active" by encouraging the animals to move along a humidity and temperature gradient out of the soil (e.g., Macfadyen, 1962; Crossley and Blair, 1991), or "passive" by using physical properties to separate animals from mineral soil (e.g., Walter et al., 1987). See Edwards (1991) for a review of these methods and their variants. An alternate sampling method employs litterbags containing leaf litter, which are placed in the field at the beginning of the season and then retrieved through time (Crossley and Hoglund, 1962). Using this technique, it is possible to identify microarthropod groups associated with various stages of litter decay.
FIGURE 25.6   A high-efficiency extractor for core samples of soil microarthropods. Soil cores contained in aluminum sleeves are inverted and heated from above with 5 W lights. Fauna are collected in funnels below. (Reprinted from Crossley, D.A., and J.M. Blair. 1991. A high-efficiency, low-technology tullgren-type extractor for soil microarthropods. Agric. Ecosyst. Environ. 34:187–192, Copyright (1991), with permission from Elsevier.)

TABLE 25.6 Formulations of Microarthropod Storage Fluids, Clearing Agents, and Slide Mounting Media

Storage fluids	Ethyl alcohol (70%–95%) Oudeman's fluid: glycerin (5 parts); 70% ethyl alcohol (87 parts); and glacial acetic acid (8 parts)
Clearing agents	Lactic acid Nesbitt's fluid: chloral hydrate (40 g); lactic or hydrochloric acid (2.5 mL); and distilled water (25 mL)
Mounting media	Heinze PVA: Stir polyvinyl alcohol powder (10 g) in distilled water (60 mL) under low heat; add lactic acid (35 mL) then glycerol (10 g), stir until smooth; cool until lukewarm; dissolve chloral hydrate (100 g) into mixture; filter or centrifuge to remove impurities

Extracted microarthropods are typically stored in 70% ethanol (Table 25.6) and may be sorted into major taxa with the use of a dissecting microscope at 20 times magnification. Major groups of mites and many families of collembolans are readily identified, once their basic morphology and characteristics are learned. Identification to species requires slide-mounted material. Slide mounts can be made directly from alcohol, although heavily sclerotized specimens may require preliminary clearing (Table 25.6). Identification of North American microarthropod species is difficult because of the large number of poorly described or unnamed species (Behan-Pelletier and Bissett, 1992). While it is essential that identifications be verified by an expert taxonomist specializing in the taxon, enumeration of each of the major taxa (above) is often adequate for comparative studies of soil microarthropods.

The abundance and richness of microarthropods in organic soil and litter samples can be overwhelmingly high for study, necessitating processing strategies that reduce workloads and expert involvement. Sample volume reduction can be used with minimal loss of information (Santos et al., 2008). Alternatively, molecular methods commonly used for bacteria and fungi can "probe" for soil microarthropods in a sample (Gibb et al., 2008; Hamilton et al., 2009; Wu et al., 2009). These methods have the potential to vastly reduce required workloads in soil investigations, but with some important trade-offs. Only species richness estimates (not species identities) are possible unless the analysis is coupled to a database of expert identifications with corresponding molecular profiles, and there is no defensible method to derive abundances from the analysis. Also, the methods often employ sample sizes of soil (1–2 g) that are under-representative of the scale an assemblage of microarthropods exist at. This can be remedied with the use of traditional extraction methods to concentrate microarthropods into a smaller volume of fluid.

It is difficult to answer basic ecological questions about soil microarthropods (e.g., "what do they eat?") because direct observation in situ is practically impossible. Feeding preference studies, observations of gut contents, radioisotope tracers, and enzymatic analyses have all been used to infer ecological roles of a limited set of taxa. Analysis of stable isotopes and fatty acids has recently added resolution and some surprises to our understanding of microarthropods. For example, energy flowing through microarthropods (and the "detrital" food web in general) may originate primarily from roots and root exudates, not litter as has been traditionally assumed (Garrett et al., 2001; Ostle et al., 2007; Pollierer et al., 2009). Also, we now know that supposedly generalist fungivore/detritivore microarthropod species have highly specific, consistent diets (Schneider et al., 2004; Chahartaghi et al., 2005; Illig et al., 2005; Ruess et al., 2005). Low temperature scanning electron microscopy (LTSEM) and x-ray tomography may also prove useful in soil microarthropod ecological research. With LTSEM, researchers are able to observe ecological interactions by literally freezing the animals in situ (Achor et al., 2001), while x-ray tomography and holotomography allows researchers to noninvasively study microarthropods internally in three dimensions (Heethoff and Cloetens, 2008; Heethoff et al., 2008).

25.4 Macroarthropods

M.A. Callaham, Jr.

D.A. Crossley, Jr.

David C. Coleman

25.4.1 Introduction

The macroarthropods are those large enough to be sampled as individuals, in contrast to the microarthropods that are sampled by extraction from a fragment of habitat (Section 25.3; Dindal, 1990; Borror et al., 1992; Arnett, 1993). Although smaller macroarthropods overlap in size with the larger microarthropods (Figure 25.2), the distinction between them is a practical one, based on method of sampling. A functional difference lies in their impact on soils. Macroarthropods are capable of restructuring soil profiles or relocating large amounts of soil, whereas microarthropods typically inhabit (and do little to modify) the existing pore spaces in soil (Coleman et al., 2004). Two insect groups, ants and termites, are responsible for major disruptions of soil profiles and have thus been classified as ecosystem engineers (Jones et al., 1997; Jouquet et al., 2006), while other macroarthropods may cause some disturbance. Examples include emergence tunnels of periodical cicadas (Insecta: Homoptera) (Whiles et al., 2001), or chimneys made by terrestrial crayfish (Crustacea: Decapoda) in hydric soils (Welch et al., 2008).

The macroarthropods in soil systems are a highly diverse group. Most terrestrial insect orders contain species that live in the soil at some phase of their life cycle. Transient species (some Lepidoptera), are those that overwinter or pupate in surficial soil layers. Other temporary residents such as midges and other flies spend their immature stages in the soil but emerge as adults to feed elsewhere. Permanent soil residents, such as predaceous beetles, remain in the soil or on soil surfaces. Spiders (Araneae) and centipedes (Chilopoda) are numerous and important predators in soil systems (Kastan, 1978; Camatini, 1979; Kevan and Scudder, 1989; Foelix, 1996). Detrivores include millipedes (Diplopoda) and sowbugs (Isopoda) (Shachak et al., 1976; Camatini, 1979; Snider and Shaddy, 1980). Scorpions (Scorpionida) and windscorpions (Solifugae) are important predators in desert systems (Crawford, 1981; Williams, 1987). Ants fall into several feeding guilds, and are diverse, abundant, and nearly ubiquitous in tropical and temperate ecosystems (Keller and Gordon, 2009). Several groups of macroarthropods (e.g., Coleoptera, Diptera, Lepidoptera) are considered pests in agricultural systems and can cause significant economic impacts either through crop and forage damage, or through expenses associated with their control (e.g., McCracken et al., 1995; Jackson and Klein, 2006; Doğramaci and Tingey, 2009).

25.4.2 Biology and Ecology

The major groups of macroarthropods likely to be found in soil and litter samples are listed in Table 25.7. The list is not inclusive

TABLE 25.7   Major Groups of Macroarthropods

Class	Order	Common Name(s)
Arachnida	Araneae	Spiders
	Scorpiones	Scorpions
	Opiliones	Phalangids, harvestmen
	Pseudoscorpiones	Pseudoscorpions
	Solifugae	Windscorpions
Malacostraca	Isopoda	Sowbugs, pillbugs, woodlice, roly-polies
Diplopoda	Ten orders	Millipedes
Chilopoda	Four orders	Centipedes
Hexapoda	Hymenoptera	Ants, wasps
	Isoptera	Termites
	Coleoptera	Beetles, rove beetles, tiger beetles, white grubs, wireworms
	Diptera	Flies, clusterflies, midges, leatherjackets, maggots
	Lepidoptera	Armyworms, potato tuberworms
	Homoptera	Cicadas, leafhoppers
	Dermaptera	Earwigs
	Diplura	Diplura
	Protura	Protura
	Neuroptera	Antlions
	Twenty-one other orders	

because, aside from representatives of the minor orders of arachnids and insects not listed, samples may also include representatives of major orders not usually considered to be soil fauna. Grasshoppers and crickets are frequently found on the soil surface and in pitfall traps. Even caterpillars that have descended from plant canopies to pupate in soil will be sampled. In fact, nearly every free-living group of terrestrial arthropods may occasionally enter soil food webs as prey items.

The majority of the scientific literature deals with individual taxa in detail, rather than providing overviews of entire macroarthropod faunas. Where general overviews do exist, they attempt broad syntheses, often without detailed information about macroarthropods (Dindal, 1990; Borror et al., 1992). The biology and importance of some ecological groups, such as root feeders, remain poorly known (Hunter, 2001; Blossey and Hunt-Joshi, 2003; Coleman et al., 2004; Johnson and Murray, 2008).

Macroarthropod fauna vary considerably between and within types of ecosystems. Several workers have suggested that macroarthropods can be used as indicators of soil quality in agricultural or pollution contexts (Linden et al., 1994; Kuperman, 1996; Lobry de Bruyn, 1997), and others have indicated that belowground arthropod herbivores have potential for use as biological control agents for invasive plant species, but this potential is largely unexplored relative to aboveground insect herbivores (Blossey and Hunt-Joshi, 2003). Forested ecosystems in general contain macroarthropod fauna dominated by millipedes, spiders, flies, and beetles (Table 25.8). Numbers and biomass tend to be greater in hardwood than in evergreen forests, where microarthropod abundance is high (Section 25.3). Spiders, carabid beetles, and crickets are abundant in pitfall traps placed in agricultural areas (Blumberg and Crossley, 1983; House and Stinner, 1983). Most species of macroarthropods may be more sensitive to cultivation than other soil fauna, and as a result, investigations have neglected the sensitive species in favor of the abundant ones (Wolters and Ekschmitt, 1997). Spiders are the most abundant and probably the most important of the predaceous macroarthropods in terms of their impact on food webs (Ekschmitt et al., 1997; Lawrence and Wise, 2004; Wise, 2004). The ranges of macroarthropod population sizes vary widely. Considerable overlap in abundance of macroarthropod taxa among different ecosystems has been found for millipedes and centipedes, although arable land tends to contain the lower part of the range. The ranges listed in Tables 25.8 and 25.9 illustrate the differences that occur between habitat types and seasons. Adjacent forest, grassland, and agricultural lands often have markedly different species within more general taxonomic groupings such as spiders (Reichert and Lockly, 1984; Draney, 1992). The range in measured abundance is also somewhat affected by method of sampling, and the size-based definition used to delineate "macroarthropod" (Table 25.8, Figure 25.2), and additional difficulty in establishing accurate density estimates arises from the nonrandom, often highly aggregated nature of macroarthropod distribution.

25.4.2.1 Social Insects

Collectively, ants and termites are responsible for major modifications of soil. Termites are typical insects of tropical and subtropical regions and may be dominant in arid or semiarid ecosystems (Lee and Wood, 1971; Bryan, 1978; Hölldobler and Wilson, 1990; Stork and Eggleton, 1992; Bolton, 1994; Arriaga and Maya, 2007). The following soil modifications are brought about by the activities of termites: (1) physical changes of soil profiles, (2) changes in soil structure, (3) changes in the nature and distribution of organic matter, (4) changes in the distribution of plant nutrients, and (5) construction of subterranean galleries (macropores). Ants are more widely distributed than termites, occurring in most terrestrial habitats, and exhibit a variety of trophic behaviors including herbivory (foliar and seed feeding), omnivory, and many are predaceous. Their colonies are smaller than those of termites, but they are responsible for the same kinds of soil modifications. In tropical systems, leaf-cutter ants are among the most important arthropod herbivores with dramatic effects on incorporation of organic materials to belowground pools, and these ants have been implicated as affecting forest plant community dynamics when they reach high abundances (particularly in forest fragments where their predators are absent) (Terborgh et al., 2001). As predators, ants may have a considerable impact on herbivorous insects. The importance of ants as predators of insect pests has been well demonstrated in a variety of stable forest ecosystems. Close, evidently coevolved, relationships exist between some plant and ant species, but in relatively unstable, annual agroecosystems, less is known of the importance of the ants.

Numbers in parentheses indicate ranges of abundance estimates.

25.4.2.2 Myriapods

The many-legged arthropods (myriapods) are abundant in undisturbed soils of many types, but less abundant in agricultural systems (Table 25.8). Millipedes are major saprovores, feeding upon decomposing organic matter in a variety of ecosystems. Although moisture dependent, they are among the macroarthropods of desert ecosystems (Crawford, 1979). Millipedes, which are important in Ca cycling in forests, have a calcareous exoskeleton and may process 15%–20% of Ca inputs into forest floors (Coleman et al., 2004). Some millipedes are obligate coprophages, feeding on their own microbially enriched fecal matter, while others excrete noxious chemicals as a defense mechanism against predation.

Centipedes are ubiquitous and active predators in soil and litter habitats, able to run rapidly and capture small prey such as microarthropods (especially collembolans). Most are 3–5 cm in length, but tropical centipedes may exceed 30 cm. Typically, centipedes constitute about 20% of the predaceous macroarthropods in temperate forests, but the percentage is lower in subarctic, boreal, and dry forests (Albert, 1979). Species diversity is lower for centipedes than for other predators such as spiders and staphylinid beetles.

25.4.2.3 Spiders

Spiders are the most numerous of the predaceous macroarthropods in ecosystems ranging from forest to grassland to agroecosystems. The taxonomy of soil- and litter-dwelling spiders remains unsettled, especially for the numerous species in the family Linyphiidae, which contains many small soil species. Spiders, which are strictly carnivorous, are generalist feeders that attack insects but also feed upon other invertebrates, including other spiders (Wise, 1993). Despite their numbers, there is no consensus on the abilities of spiders to control insect populations (Riechert and Lockly, 1984). Spiders do not reproduce rapidly enough to keep pace with exploding prey populations. Also, many species are territorial. In forest habitats, spiders may act as a stabilizing influence on populations of forest floor invertebrates by maintaining a continual predation pressure.

25.4.2.4 Beetles

In terms of numbers of species, beetles are the largest order of insects, being found in every habitat except the oceans (Richter, 1958; Thiele, 1977). In soil systems, beetles include species that are phytophagous, saprophagous, and predaceous. Carabid, tenebrionid, and staphylinid beetles are numerous predators in disturbed and undisturbed systems alike. Together with spiders, carabids are the typical ground-surface macroarthropod predators taken in pitfall traps in agroecosystems. Other active predators included the tiger beetles (Cicindelidae) whose larvae construct belowground retreats from which they capture prey. Phytophagous beetles include the Scarabaeidae (June beetles) whose larvae feed extensively on roots. Larvae of elaterid beetles (wireworms) are important root feeders in cropping systems and in forests. Although predaceous beetles

are conspicuous, especially on the soil surface in agricultural fields, the phytophagous species are probably more important. The predaceous carabids may exert some control on caterpillars such as armyworms and similar species. Gypsy moth caterpillars, descending to the soil of the forest to pupate, may fall prey to carabid beetles in large numbers.

25.4.3 Sampling and Analysis

Macroarthropods are sampled in several ways. A good review of the general methodology used for sampling populations of soil macroinvertebrates is given in Edwards (1991). The most basic method involves delineation of an area a square meter or less followed by hand sorting organic horizons and digging to a set depth the mineral horizons of soil and collecting all macroarthropods encountered. Tullgren funnels are useful for extracting arthropods from bulk samples of soil and litter, and this technique relies on heat and light stimuli to drive organisms from the samples (Section 25.4.2.3 and Figure 25.7). It is also possible to collect subterranean macroarthropods by taking soil cores (10–15 cm diameter) and sieving them, either dry or with the use of a wet sieving apparatus. Another technique used to sample macroarthropods involves the separation of organisms from samples by taking advantage of their relatively low specific gravity and the hydrophobic properties of their cuticles. This generally involves some kind of flotation of organisms from samples in a high density liquid (usually salt or sugar solutions; Edwards, 1991).

When investigators are strictly interested in sampling the greatest number of species (i.e., sampling for diversity and not abundance or density), other sampling techniques are useful. For example, Snyder et al. (2006) found that targeted hand collecting of millipedes from sites selected a priori as being likely for encountering specimens (rather than randomly assigned spatially based approaches) produced the largest number of species in the shortest time. Another qualitative method in widespread use involves pitfall traps—cans set flush with the soil surface
FIGURE 25.7   Large Tulgreen funnels for extraction of macroarthropods from soil cores and litter.
FIGURE 25.8 A pitfall trap for surface active macroarthropods. PDB = P-dichlorobenze preservative. (Reprinted from Reichle, D.E., and D.A. Crossley, Jr. 1965. Radiocesium dispersion in a cryptozoan food web. Health Phys. 11:1375–1384. With permission from Williams and Wilkins, Baltimore, MD.)

and containing a preservative (Figure 25.8). Pitfall traps are an inexpensive sampling technique, but are not entirely quantitative, since captures depend upon the mobility of animals as well as their density. In sampling programs designed for comparison of areas or seasons, pitfall traps are a preferred method (Bater, 1996). Each of these qualitative sampling methods can be rendered semiquantitative if care is taken to standardize the time that searching or trapping is conducted and comparisons may be made on the basis of equal effort collecting for a given habitat type or experimental manipulation.

Because ants and termites are social insects, population estimation for these insects requires special techniques. Species diversity of ants is readily sampled with baited pitfall traps (Romero and Jaffe, 1989), while subterranean termites are sampled using soil cores (Lee and Wood, 1971). Termite mounds may require complete destruction. A comparative sampling technique for desert termites uses rolls of toilet paper, which are placed on the soil surface and shielded from the sun with aluminum foil (Whitford et al., 1982).

Samples may be preserved in 70% alcohol prior to sorting. Although alcoholic storage is satisfactory for storage of specimens, most entomologists prefer that insects be pinned if possible. Different insect orders are pinned in different ways, and detailed instructions for pinning and labeling techniques are given in most entomology textbooks (Borror et al., 1992).

Sorting of adult macroarthropods into major taxa is straightforward. Reference to a general entomology textbook will allow the novice to make identifications to major hexapod taxa to family levels. More detailed sorting of other macroarthropod taxa such as spiders, diplopods, and chilopods may be done with the aid of literature guides (Dindal, 1990; Ubick et al., 2005). Additionally, because samples derived from subterranean sampling will usually include immature stages of Coleoptera, Lepidoptera, and Diptera (among others), special training is usually required for identifications, although a few groups are readily recognized. North American guides for the identification of immature insects including those found predominantly in soils are found in Peterson (1967) and Stehr (2005). Identifications of adult specimens to generic and species levels will also require services of a specialist in the taxonomy of the group. There is some promise in the development of molecular-based techniques for the identification of soil organisms, but to date these have been useful only for establishing the degree of genetic diversity in a sample, and not so useful for providing clues as to the identities of organisms (Wu et al., 2009). A DNA-based technique has been used to identify the gut contents of predatory beetles (Juen and Traugott, 2006), and in the future may prove useful for identification of bulk extracted organisms as well.

Once organisms have been collected and reliably identified, the data typically are reported in terms of presence/absence, relative abundance, or frequency of occurrence (e.g., from pitfall trapped collections), or when sampling is conducted in a spatially explicit way, in terms of density (individuals m^{-2}) or biomass (g ash-free dry mass m^{-2}). It is common for researchers to use abundance and identity data to calculate community measures such as indexes of diversity, evenness, similarity, or rank abundance. This kind of analysis is typically performed when sampling has been conducted in areas that have experienced different land uses or been subjected to experimental treatments that are expected to have influence on macroinvertebrate community structure (e.g., Decaëns et al., 2004; Callaham et al., 2006). Another useful and increasingly common technique for analyzing soil macroinvertebrate community structure is the use of multivariate statistical analyses to describe the dimensionality and variation in assemblages from different experimental treatments or habitats (e.g., Decaëns et al., 1998; Siira-Pietikäinen et al., 2003).

Because the net effect of macroarthropods on ecosystem functions such as decomposition or primary productivity are often dependent in some part on indirect effects through trophic interactions, ecologists are interested in food web structure and energy and nutrient flows through these webs. However, for subterranean linkages in food webs, observations have been difficult to make without fairly intensive disturbances to the system under scrutiny. Relatively recent developments in mass spectroscopy have improved this situation, and made it possible to process a large number of samples at reasonable cost for stable isotopic signatures of invertebrate tissues. This has greatly facilitated the determination of dietary relationships between individual taxa of belowground consumers (e.g., Callaham et al., 2000; Traugott et al., 2008; Seeber et al., 2009) as well as trophic relationships in soil food webs with better resolution than ever before (Halaj et al., 2005; Elfstrand et al., 2008), and this technology provides a fruitful avenue for future research on these organisms.

Finally, further recent advances in the soil food web and trophic interaction arena are due to molecular techniques that can achieve species-specific resolution for the analysis of gut contents (particularly useful in the analysis of gut contents of predators). These molecular approaches are of two basic types—those that utilize monoclonal antibodies and enzyme-linked immunosorbent assays (ELISA) to detect species (or group)-specific proteins from environmental samples (e.g., McKemey et al., 2006; Thomas et al., 2009), and those that utilize DNA-based assays where primers for suspected prey items are used to amplify the DNA of gut contents of predatory macroarthropods (Juen and Traugott, 2007; Kuusk et al., 2008). A good review of the methods for DNA-based approaches to assessing predator–prey interactions, along with a detailed discussion of challenges, is given in King et al. (2008). Both the DNA and ELISA techniques allow a level of resolution that is unprecedented in determining the diets of predators in soil food webs, and the ELISA technique has even been used to estimate densities of soil invertebrates (slugs) with reasonable accuracy at with greater speed than conventional estimation methods (McKemey et al., 2006). Fournier et al. (2008) conducted a comparative study to evaluate the relative sensitivities of ELISA and PCR techniques for detecting a specific prey item in the diets of 30 predator taxa, and found that after initial outlay of time and money for development of the antibody used in the assay, the ELISA technique was faster, more sensitive, and less expensive to process samples. Although these approaches promise major advances in future understanding of soil food webs, and have been used to good effect in aboveground contexts, they are in their infancy as applied to soil systems, and many of the methodological details are still under development (see King et al., 2008; von Berg et al., 2008). Thus, a great deal of work remains to be done in terms of methods development (e.g., production of appropriate primers and antibodies for detection of the full diversity of available food items in soil food webs), and this work must be accomplished before the potential of molecular techniques can be completely realized in soil ecological studies. Nevertheless, with continued growth in the number of investigators using these techniques, and with continued advances in molecular methodology, it is likely that the immense diversity and complexity of the soil biota will be understood with greater detail than had previously been possible.

25.5 Enchytraeidae—Oligochaeta

P.C.J. van Vliet

Paul F. Hendrix

25.5.1 Introduction

The Enchytraeidae is a family of Oligochaetes that occur in terrestrial, littoral, and aquatic habitats. A total of some 600 species are now known worldwide, from the tropics to polar latitudes (Dash, 1990; Vaculik et al., 2004; Christensen and Dozsa-Farkas, 2006). Enchytraeids are mostly pale-colored and are anatomically similar to earthworms (only smaller). Their length ranges from 5 cm to less than 1 mm. Larger enchytraeids (up to 60 mm long) have been found in subarctic soils from the unglaciated portion of the northern Yukon (Canada) (Smith et al., 1990).

Of the Oligochaeta, earthworms (Lumbricidae) have been the subject of most studies. Enchytraeidae (also known as "potworms") have been studied less frequently although they are distributed throughout the world. The biology and ecology of enchytraeids have become somewhat better known during the

last 30 years, especially in Europe. This intensification was partly due to the systematic revision of this family for European species (Nielsen and Christensen, 1959, 1961, 1963), the development of efficient methods of extraction of enchytraeids from soil (Nielsen, 1953; O'Connor, 1955), and the fact that they were very abundant in certain ecosystems and were expected to have an important role in nutrient cycling and soil structure formation.

In the past two decades, enchytraeids have become widely used as test organisms for ecotoxicological evaluation of soil contaminants (Didden and Römbke, 2001; Römbke, 2003), and recent studies suggest that they may be sensitive indicators of effects of climate change (Briones et al., 2007; Maraldo et al., 2008).

25.5.2 Taxonomy and Morphology

Currently the Nielsen and Christensen (1959, 1961, 1963) monographs for European species are used for the identification of enchytraeids, although many more genera and species have been found since. In 2003, Schmelz (2003) described the taxonomy of the dominant *Fridericia* genus. Schmelz has also submitted a new key to European terrestrial and freshwater species of enchytraeids (Schmelz and Collado, 2010). A simple key to the most common genera of Enchytraeidae can be found in the *Soil Biology Guide* (Dash, 1990). Taxonomic literature on North American Enchytraeidae is fairly sparse and no good key is available.

The easiest way to observe and identify enchytraeids is by getting them to clear their gut in a Petri dish in a cool place. A sexually mature worm (alive) can then be transferred to a drop of water on a slide and covered with a cover slip. Most of the structures, shown in Figure 25.9, are fairly transparent in live worms and can be examined at a 100–400× magnification.

The known genera of enchytraeids are mentioned in Table 25.10. Two-thirds of the genera can be found in soil. Information (when available) about the habitats of the other genera is mentioned as well.

25.5.3 Collection and Extraction Methods

For quantitative sampling purposes, enchytraeids can best be sampled with a cylindrical soil corer, which will keep the soil intact. Different studies have shown that the optimum sampler size is 5–7.5 cm in diameter (Lal et al., 1981; Didden et al., 1995). Because enchytraeids are clustered in soil (see later), sufficient replicates need to be taken, to get a good estimate of population size and composition. However, the size and number of the sampling units are mostly chosen as a compromise between accuracy of the abundance estimates and the amount of work involved (Didden, 1993).

Hand sorting of enchytraeids out of soil is possible, but the efficiency of this labor-intensive method is very low. Enchytraeids are often covered with small sand grains and organic particles (Ponge, 1984), making them hard to distinguish from soil material. Small animals are also hard to recover with the hand sorting method.
FIGURE 25.9 Morphological characters of an enchytraeid worm. amp., ampulla; an.sept., ante-septal; br., brain; d.bv.o., dorsal blood vessel origin; ec.dt., ectal duct; e.dt. ental duct; eff.dt., efferent duct; es., esophagus; es.int.tr., esophageal intestinal transition; neph., nephridia; oc., oocyte; pha., pharynx; p.b., penial bulb; pepneph., peptonephridia; p.sept., postseptal; se., setae; sept.g., septal gland; sm.v., seminal vesicle; sp. spermatheca; sp.dt., sperm duct; sp.f., sperm funnel; t., testes. (Reprinted from Dindal, D.L. (ed.), *Soil Biology Guide*, Wiley Interscience, New York, 1990.)

The most common method used to extract enchytraeids from soil is the O'Connor wet funnel method (O'Connor, 1955). In this method, a soil slice (maximum 3 cm thick), resting on a sieve in a funnel filled with water, is exposed to light and heat. In 3 h, the light intensity is increased gradually until the soil surface has reached a temperature of 45°C. Enchytraeids respond to the light and heat by moving away from the source and pass through the sieve into the water below. Figure 25.10 shows a modified O'Connor extractor apparatus. It consists of a box containing 32 funnels above which 25 W bulbs are generating enough heat in 3 h to get the soil surface to the correct temperature.

Recently, a modified extraction method has been proposed (Graefe, 1973; Schauermann, 1983). In this method

TABLE 25.10 Enchytraeid Genera and Their Occurrence in Soil

Genera Occurring in Soil	Other Genera	Environment
Achaeta	*Aspidodrilus*	Epizoic on earthworms
Bryodrilus	*Barbidrilus*	Freshwater
Buchholzia	*Enchylea*	Only found in enchytraeid culture
Cernosvitoviella	*Enchytraeina*	Marine
Cognettia	*Grania*	Marine
Enchytraeus	*Pelmatodrilus*	Epizoic on earthworms
Enchytronia	*Propappus*	Freshwater
Fridericia	*Randidrilus*	Marine
Guaranidrilus	*Stephensoniella*	Marine
Hemienchytraeus		
Hemifridericia		
Henlea		
Isosetosa		
Lumbricillus		
Marionina		
Mesenchytraeus		
Oconnorella		
Stercutus		
Tupidrilus

FIGURE 25.10 Enchytraeid extractor after O'Connor (1955). The sieves with soil are completely submerged in water; after 4 h in the dark the light intensity is increased in 3 h from very dim to full bright.
FIGURE 25.11 Part of an enchytraeid extractor after consisting of a sieve (1 mm mesh) held in a bowl filled with water, developed by Graefe (1973).

(Figure 25.11), enchytraeids are extracted from soil without heat. The total extraction time is extended from 3 h to several days for soils rich in organic matter and up to 2 weeks for mineral soils. The length of the extraction period is determined by the risk of an oxygen deficit and of dying of larger individuals.

A comparative study of the two methods (Didden et al., 1995) has shown that a better extraction is obtained without heating. The length of the cold extraction period and the total extraction time had a significant positive influence on the extraction efficiency. Also, the Graefe method is cheap and easy to set up. However, due to its long extraction time, the method is not very appropriate for studies where large numbers of samples are taken or where samples are taken at short time intervals. In those cases, the faster O'Connor method (maybe modified with a longer settling time before the heated extraction starts) might be more appropriate (Didden et al., 1995).

25.5.4 Life History: Reproduction

Several types of reproduction strategies are known in enchytraeids (Table 25.11). Reproduction occurs mostly through the formation of cocoons. A cocoon contains one or more eggs, depending upon the individual and the species. Some enchytraeids cover their cocoons with a layer of organic debris and

TABLE 25.11 Reproduction Strategies in Enchytraeids

Reproduction	Description	Genera/Species
Only sexually, all during the year possible	Irregular reproduction periods, specimens with eggs can be found any time of the year	Many *Fridericia* sp., most *Enchytraeus* sp., *Henlea* sp., *Enchytronia* sp., *Marionina* sp., *Achaeta* sp.
Only sexually, become mature once a year	Thereafter, they regress and stay in rejuvenile state till the next reproduction period	*Mesenchytraeus* sp., *S. niveus*
Parthenogenesis	Egg development without fertilization	*Lumbricillus* sp. and *Fridericia* sp.
Fragmentation		*Buchholzia* sp. and *Cognettia* sp.
Self-fertilization		*E. buchholzi, E. bulbosis*

Source: After Dósza-Farkas, K. 1996. Reproduction strategies in some enchytraeid species, p. 25–33. *In* K. Dósza-Farkas (ed.) Newsletter on Enchytraeidae No. 5. Eötvös Loránd University, Budapest, Hungary.

sand grains, which makes them hard to find by predators in the soil (Christensen, 1956). Covering the cocoons might also increase drought resistance of the cocoons (Dash, 1990). Cocoon production is more rapid in young mature than older worms. Depending on the species and the temperature, the duration from cocoon hatching to maturity lasts about 65–120 days. The maximum lifespan of enchytraeids is assumed to be 1 year (Dash, 1990).

Parthenogenesis, self-fertilization, and fragmentation are reproduction strategies often used by cosmopolite and widespread species. These strategies allow animals to survive under particularly unfavorable conditions and enhance their chances to successfully colonize new habitats (Dósza-Farkas, 1996).

25.5.5 Food Preferences

It is known that enchytraeids ingest mineral particles, leaf litter, fungi, bacteria, oats and yeast, seaweeds, and sewage. Dash et al. (1981) and Urbášek and Chalupský (1991) found that enchytraeids were capable of digesting di- and some polysaccharides in food, but that most complex plant substances would become available through microbial decomposition. Related to their food source, different species have different amounts of certain enzymes. For instance, litter-inhabiting species such as *Fridericia galba* and *Cognettia sphagnetorum* manifested higher activities of enzymes to break down polysaccharides, while *Enchytraeus albidus*, which prefers mostly compost, had higher proteolytic activity (Urbášek and Chalupský, 1991). In food preference experiments, Dósza-Farkas (1982) showed that enchytraeids preferred old and microbially decomposed leaves over fresh leaves. However, consumption of the partially decomposed leaves differed by species. According to Toutain et al. (1982), enchytraeids only consumed the epidermis and parenchyma cells of leaves, while avoiding the veins. After passage through their guts, the structure of the material had not changed much; only bacteria and fungi earlier present on the leaves were digested. Brockmeyer et al. (1990) used radiolabeled food sources to determine food preferences of two enchytraeid species and found that enchytraeids were not able to break down the cell walls of the fresh plant material, while the muramic acid cell walls of the microorganisms were no barrier to the worms' digestive capabilities. Using ^{14}C dating techniques, Briones and Ineson (2002) found that enchytraeids mostly assimilated soil carbon that was 5–10 years old regardless of the depth at which the enchytraeids were collected.

Looking at the feeding habits of *C. sphagnetorum*, Persson et al. (1980) considered enchytraeid communities to be 50% saprovorous, 25% fungivorous, and 25% bacterivorous. This differentiation is often used in production ecological studies. It seems however that microbivory is underestimated, because some species are well adapted to digest microbes, while no species have been found that produce sufficient amounts of enzymes to decompose complex plant compounds. Therefore, it seems to be more realistic to assume that an enchytraeid community contains 80% microbivorous and 20% saprovorous feeders (Didden, 1993).

25.5.6 Enchytraeidae Abundances and Distributions

Enchytraeidae are common in cultivated soil but reach their highest abundances in acid soils with a high organic matter content (e.g., O'Connor, 1957; Peachey, 1963). Large populations have been found in cold and temperate moist habitats, but this may be more a function of the greater amount of data available from Europe than of environmental conditions. Table 25.12 gives an overview of average annual abundances of enchytraeids in various habitats throughout the world. Didden (1991) found no correlations between enchytraeid densities on one hand and annual precipitation, annual temperature, and acidity of the soil on the other.

It is well documented that enchytraeids occur in aggregated distribution patterns (Nielsen, 1954; Peachey, 1963; O'Connor, 1967; Abrahamsen, 1969; Abrahamsen and Strand, 1970; Nakamura, 1979, 1982). Chalupský and Lepš (1985) demonstrated that enchytraeids occur in multispecies aggregation centers. It seems therefore that aggregations are not due to sudden breeding from cocoons but are environmentally conditioned (e.g., physical conditions, food availability).

The vertical distribution of enchytraeids in a soil is mostly related to the organic material distribution in the soil profile. In most natural habitats, up to 90% of the population occurs in the upper layers where most of the organic matter is located. Persson et al. (1980) found 57% of the enchytraeid biomass in the organic layers in a Scots pine forest. O'Connor (1957) found that more than 50% of the enchytraeids occurred in the humus layer of a Douglas fir coniferous forest.

The importance of organic matter for the vertical distribution of enchytraeids can easily be demonstrated in agricultural ecosystems. In pastures and no-tillage field, where the organic matter is not plowed in, enchytraeids occur mostly in the top layer. On the other hand, in tilled agricultural fields, where the organic matter is mixed throughout the soil profile, enchytraeids are found evenly through the whole plow layer (Lagerlöf et al., 1989; Didden, 1991; van Vliet et al., 1997).

The vertical distribution of enchytraeids is also influenced by changes in soil moisture content and temperature. Enchytraeids are known to react rapidly to changes in soil moisture (Nielsen, 1955a; O'Connor, 1967). In low-moisture soils, enchytraeids lose water quickly, which can be prevented by deeper migration (Nielsen, 1955b). Springett et al. (1970) showed that enchytraeids were able to move vertically as the soil water content changed, covering up to 6 cm in a few hours. Apart from the distribution of organic material and environmental variables, the vertical distribution of enchytraeids may also be species specific.

TABLE 25.12 Enchytraeid Abundances (Annual Average Number m^{-2}) in Different
Biotypes and Countries

Biotope	Country	Abundance (Number m^{-2})	Reference

Dósza-Farkas (1973) findings for a Hungarian forest revealed that *Stercutus niveus* Michaelsen, 1888 had a pattern of distribution and migration differing substantially from that of other species present, pointing out the importance of knowing species composition and behavioral characteristics of the enchytraeid community.

Nielsen (1955a) determined that the seasonal trends in population densities of enchytraeids are caused directly or indirectly by external factors and do not arise from any inherent rhythmic fluctuation. According to O'Connor (1957), seasonal trends in enchytraeid numbers can be predicted from climatological data. In a temperate oceanic climate, soil moisture would be sufficient for breeding during the complete year, resulting in a generally high density of enchytraeids, which would be decreasing in winter, due to temperatures too low for breeding. A south continental climate would have low abundances in summer and fall when temperature is too high and moisture too low to be suitable for breeding. Maximum densities would occur in winter and spring. Yeates (1986) found a significant correlation between enchytraeid

abundances in a pasture in New Zealand and soil moisture and temperature at the sampling occasion or with these environmental data from 3 weeks earlier. Abrahamsen (1972) found that enchytraeid abundances were correlated with soil moisture but also with vegetation type. Environmental conditions can cause changes in the active state of the animals (e.g., cocoons, diapause) and/or accelerate or retardate the reproductive cycle (Didden, 1993).

25.5.7 Enchytraeids and Organic Matter Decomposition

Abrahamsen (1990) studied the influence of *C. sphagnetorum* on N mineralization in homogenized mor humus. He found that temperature, moisture, and the presence of enchytraeids significantly influenced N mineralization. The effect of *Cognettia* on N mineralization was most important in the very moist soil where the species reached its greatest abundance. Presence of enchytraeids in the systems increased the level of NH_4^+ and NO_3^- by 18%. Almost 40% of this difference was explained by the decomposition of dead enchytraeids. Didden (1995) also found that the decomposition of litter and nitrogen mobilization was enhanced in the presence of enchytraeids. Enchytraeids have also been shown to stimulate nitrogenase activity in soil (Šimek et al., 1991). Cole et al. (2002) estimated that enchytraeids accounted for up to 26% of dissolved organic carbon (DOC) in blanket peat bogs; a positive relationship between soil temperature and enchytraeid abundance suggested that climate warming of 2.5°C could result in an 11% increase in enchytraeid-induced release of DOC.

Enchytraeids can influence decomposition processes by affecting soil microorganisms in several ways. Grazing might lead to a younger microbial population, that is, a population with a higher metabolic activity (Sparling et al., 1981). Also due to the microbivorous and saprovorous feeding of enchytraeids, the release of nutrients from the microbial biomass is promoted. Williams and Griffiths (1989) showed that enchytraeids enhanced the leaching of nutrients out of columns by reducing nutrient immobilization in the microbial biomass. The activities of enchytraeids may also change the species composition of the microbial community and may inhibit the growth of fungal hyphae. In a laboratory experiment, Forster et al. (1995) showed that enchytraeids increased the CO_2 production and decreased microbial biomass. Apparently, the metabolic quotient of the microorganisms was increased by the enchytraeids.

Enchytraeids seem to be more efficient in promoting mineralization than microarthropods. Sulkava et al. (1996) found in microcosms with microorganisms and enchytraeids and with and without microarthropods that the amount of NH_4^+ mineralized was strongly correlated with enchytraeid biomass.

Wolters (1988) demonstrated that the enchytraeid species *Mesenchytraeus glandulosus* Levinsen, 1884 had a large influence on litter decomposition processes in beech forest soil. On the one hand, the enchytraeid promoted decomposition, for example, through an increase in the inoculation capacity of the microflora and through alteration of the physiochemical conditions of the substrate. On the other hand, *M. glandulosus* was capable of decreasing mineralization rates, for example, by reducing the number of microbial inhabitants in the environment and probably by occluding the products synthesized by soil fungi in their feces. Therefore, the net effect of the enchytraeids on litter decomposition must be regarded as the result of both promotory and inhibitory influences on the soil microflora.

Golebiowska and Ryszkowski (1977) found that tillage shifted the proportional importance of the Annelida from earthworms to the metabolically more active enchytraeids. They concluded that in conventionally tilled fields Enchytraeidae were important in the process of organic matter mineralization due to their high respiration. Hendrix et al. (1986) came to a similar conclusion: they hypothesized that enchytraeids were more important in the detritus food web in conventionally tilled than in no-tillage fields.

Kasprzak (1982) concluded that in cultivated fields in Poland the contribution of enchytraeids to the process of organic matter mineralization was much greater than that of earthworms. The percentage of total soil respiration that can be attributed to enchytraeid activity varied from 0.4% in a potato field in Poland (Golebiowska et al., 1974) to 3.2% in a sugar beet field in the Netherlands (Didden, 1991).

So, enchytraeids can influence the decomposition of organic matter by comminution of the material, which will enhance decomposition by the microbial biomass, by their selective grazing of the microbial population, by incorporating soil organic matter (SOM) into soil and soil aggregates (see in the following section) (e.g., Toutain et al., 1982; Ponge, 1984; Toutain, 1987; Wolters, 1988; Dash, 1990), by the dispersal of spores and fungal propagules and by immobilization of nutrients in their biomass (Zachariae, 1964; Abrahamsen, 1990; Didden, 1993).

25.5.8 Enchytraeids and Soil Structure

Enchytraeids excrete fecal pellets consisting of fine particles, with little cellulose plant residues. In coniferous forests, these pellets contain a considerable portion of humus (Zachariae, 1963), while in mineral soils the fecal pellets are more sponge-like structures in which humus and loamy parts are combined (Kasprzak, 1982). Fecal pellets produced by enchytraeids have been described by several authors (Zachariae, 1964; Babel, 1968; Rusek 1975, 1985). Babel (1968) measured the longitudinal axis of excrements as being between 40 and 100 μm (average 60 μm) long. Didden (1990) concluded that enchytraeids have a positive effect on the aggregate stability in the 600–1000 μm fraction. These aggregates might have been partly composed of enchytraeid excrements with a size of about 200 μm. However, he observed no significant effects of enchytraeids on the distribution of water stable aggregates. Vaculik et al. (2004) found that enchytraeids consumed cyanobacteria in biological crusts on granite outcrops in tropical forests and savannas and formed a humus layer consisting of fecal pellets below the crust; they concluded that this accumulated organic

matter facilitates plant succession. In the O horizon of forest soils, enchytraeids are secondary decomposers of the larger excrements of soil macrofauna (Rusek, 1985). They make narrow channels in the large spongy earthworm excrements (Zachariae, 1964) and mix organic aggregates into mineral soil (Karroum et al., 2005). A number of researchers (e.g., Zachariae, 1964; Babel, 1968; Pawluk, 1987) have pointed to the occasionally large numbers of enchytraeid fecal pellets in mor and moder humus soils. When high densities of enchytraeids are present in soil ecosystems, their fecal matter may be important for SOM dynamics and changes in soil structure. Encapsulation of organic substances into fecal pellets will protect this material from extensive decomposition. Also these microaggregates may in turn serve as building blocks for macroaggregates (Tisdall and Oades, 1982).

Many enchytraeid researchers (e.g., O'Connor, 1967; Ponge, 1984) have mentioned the transport of mineral particles by enchytraeids, either by ingestion or attached to the body surface. van Vliet et al. (1995) calculated the amount of soil ingested by enchytraeids in an agricultural field and in rhododendron-oak forest ecosystems in the United States. In the agricultural field, enchytraeids ingested 2180 g m^{-2} year^{-1} of mineral soil. In the forests, only about 400 g m^{-2} year^{-1} of soil was ingested. Based on these estimates, enchytraeids transported 1% and 0.5% of the soil volume (0–15 cm) in the agricultural field and forest, respectively. The enchytraeid community in the agricultural field was composed for more than 50% of large *Fridericia* enchytraeids, which can contain large quantities of soil in their guts. It seems that, due to the species-specific differences between the forest and the agricultural field, the effect of enchytraeids on soil structure will be greater in agricultural fields. However, Didden (1990) found that the amount of soil transported by *Enchytraeus buchholzi* through ingestions was very low, about 0.001%–0.01% of the total soil volume. The large difference between these two measurements is mainly due to different methods of determining the amount of ingested soil, but also due to species-specific differences.

The burrowing activity of enchytraeids in soil is poorly known. Górny (1984) stated that enchytraeids were unable to burrow channels and did not use earthworm channels for penetrating deeper layers of the soil; for vertical migration, enchytraeids were dependent upon the smaller pores present in the soil. Alternatively, Jegen (1920) and Rusek (1985) concluded that enchytraeids can make active microtunnels in the soil matrix. Standen (1984) suggested that large enchytraeid species, like *F. galba*, formed burrows and transported or deposited material as feces to a depth of 3.5–4.0 cm. Species of other genera did not form visible burrows but material was transported 0.5 cm in some cases. Didden (1990) concluded that *Enchytraeous bucholzi* Vejdovsky, 1879 increased pore continuity and raised the volume of pores corresponding to their body size (size 50–200 μm). His analysis of thin sections led to the conclusion that enchytraeids removed pore necks.

Observations of enchytraeids kept in small microcosms constructed of a thin layer of soil sandwiched between glass plates have led to the conclusion that enchytraeids do make channels in soil (van Vliet et al., 1993). A later experiment (van Vliet et al., 1997) showed that in the presence of incorporated organic matter, enchytraeids increased the hydraulic conductivity of a soil column. The impact of enchytraeids on hydraulic conductivity, however, depended not only on the incorporation of organic matter in the soil but also on the number of enchytraeids present and the duration of the experiment.

Overall, it seems reasonable to assume that enchytraeids affect soil structure through their fecal pellets and their burrowing capacity. However, the total effect of enchytraeids on soil structure in an ecosystem depends on the species composition of the enchytraeid community, enchytraeid abundances, and on environmental conditions.

25.6 Earthworms

P.C.J. van Vliet

Paul F. Hendrix

M.A. Callaham, Jr.

25.6.1 Introduction

Among the soil fauna, earthworms are perhaps the most widely recognized and, along with ants and termites, function as ecosystem engineers with significant effects on soil structure and processes (Lavelle and Spain, 2001; Wardle, 2002). For these reasons, earthworms have been intensively studied for their potential benefits in agriculture, waste management, and land reclamation. The scientific literature on earthworms dates back over 200 years to the taxonomic description of *Lumbricus terrestris* by Linnaeus (1758). The modern era of earthworm research, in the context of soil science, began with Darwin (1881) and a vast literature has accumulated since then. Reviews of the literature from the past several decades can be found in Satchell (1983), Lee (1985), Dindal (1990), Curry (1994), Hendrix (1995), Edwards and Bohlen (1996), Lavelle et al. (1999), Lavelle and Spain (2001), and Edwards (2004). This chapter draws from these and other works to give a brief overview of earthworm biology, ecology, methods of collection, and analyses of earthworm tissues in food-web studies or for advanced systematic and taxonomic work.

25.6.2 Basic Taxonomy

Earthworms are classified within the phylum Annelida, class Clitellata, and subclass Oligochaeta (increasingly, Crassiclitellata). Seventeen families are usually recognized worldwide, making up the semiaquatic and terrestrial forms commonly known as earthworms (Jamieson et al., 2002). Approximately 3700 species of these megadrile oligochaetes have been described, and it is estimated that total global species richness may exceed 7000 (Reynolds, 1994; Fragoso et al., 1999; Lavelle and Lapied, 2003). Earthworm families along with their biogeographic origins are listed in Table 25.13. This table also includes the family Enchytraeidae, which is discussed in Section 25.5. Although the taxonomy and systematics of earthworms is

TABLE 25.13 Classification and Regions of Origin of Major Families of the Terrestrial Oligochaetes

Phylum: Annelida		
Class: Clitellata		
Subclass: Oligochaeta (Crassiclitellata)		
Order: Haplotaxida		
Suborder: Enchytraeina		
Family:	Enchytraeidae	NH, SH
Suborder: Lumbricina		
Family:	Lumbricidae	NH—NA, EU
	Komarekionidae	NH—NA
	Sparganophilidae	NH—NA
	Lutodrilidae	NH—NA
	Megascolecidae	NH, SH—NA, SA, OC, AS
	Glossoscolecidae	SH—SA
	Eudrilidae	SH—AF

now reasonably stable at the family and generic level, there has long been confusion and controversy associated with certain groups in terms of species names. This situation results in part from the remarkable variability in external physical characters for some groups (e.g., the lumbricid genus *Aporrectodea*) that are reliable for taxonomic diagnoses for other groups (e.g., the lumbricid genus *Lumbricus*). Likewise, the frequent occurrence of parthenogenetic (asexual) reproduction in some groups, with variable reduction of male reproductive parts that are also used for taxonomic diagnosis, has resulted in different morphotypes of a single species being named as several species (e.g., the megascolecid genus *Amynthas*; Gates, 1972). It is to be hoped that advances in genetic and molecular techniques will provide resolution for many of these problems, but this work is just under way (see Briones et al., 2009; Chang et al., 2009; Dupont, 2009). Further information on earthworm taxonomy and biogeography can be found in Reynolds (1977, 1994, 1995), Sims (1980), Jamieson (1981), Gates (1982), Hendrix (1995), James 1995, Edwards and Bohlen (1996), Sims and Gerard (1999), Omodeo (2000), Jamieson (2006), and Hendrix et al. (2008).

The families Lumbricidae and Megascolecidae are ecologically the most important in North America, Europe, Australia, and Asia, while the families Glossoscolecidae and Eudrilidae are prevalent in South America and sub-Saharan Africa, respectively. Species from several of these families have been introduced worldwide by human activities and now dominate the earthworm fauna in many areas. Such "peregrine" or "anthropochorous" species are highly successful in agricultural or otherwise disturbed areas and often show significant effects on soil processes (Lee, 1985; Edwards and Bohlen, 1996; Hendrix and Bohlen, 2002). Whether introduced earthworms displace native species or occupy areas devoid of native species due to disturbance is a subject of debate (Lee 1961; Kalisz and Wood, 1995). Earthworm invasion biology and ecology have become topics of keen interest recently (Bohlen et al., 2004; Hendrix, 2006; Hendrix et al., 2008).

25.6.3 Biology and Ecology

Earthworms are elongated, cylindrical, segmented invertebrates, ranging in length from a few millimeters to 1.4 m, such as the giant Australian *Megascolides australis*. They consist of a relatively simple, tube-within-a-tube body plan, the internal tube comprising the alimentary canal. The body segments are separated by septa and are filled with coelomic fluid that provides a dynamic, hydrostatic "skeleton" for locomotion. When fully hydrated in free water, earthworm body weight may consist of 80%–90% water, but under ideal soil moisture conditions water content is typically 65%–75% (Lee, 1985). Water is lost from the body as mucus secretions onto the body surface from epidermal gland cells. Respiration occurs through the moist integument, where blood in subcuticular capillaries absorbs oxygen that is transported throughout the body in a closed vascular system driven by a series of muscular heart-like structures. Earthworms are hermaphroditic, each individual carrying male and female reproductive organs, but a number of species display

parthenogenesis. During amphimictic reproduction, sperm is exchanged between two individuals, stored in spermathecae, and later released along with eggs into cocoons secreted by the glandular clitellum, a characteristic thickening along several anterior segments. Single or multiple hatchlings emerge from cocoons after a period of embryological development determined by species and prevailing environmental conditions. Further details of earthworm biology can be found in Wallwork (1983), Lee (1985), Edwards and Bohlen (1996), and Sims and Gerard (1999).

Earthworms occur worldwide in most areas where climatic conditions are favorable for at least part of the year (all but desert and polar conditions); temperature is the main controlling factor globally, whereas soil moisture strongly influences local patterns of abundance and distribution (Lee, 1985; Curry, 2004). Across this range of habitats, earthworms display a wide array of morphological, physiological, and behavioral adaptations to environmental conditions. During unfavorable periods (e.g., drought), many species are able to enter a temporary dormant state (aestivation or diapause) or produce resistant cocoons that can hatch when conditions improve.

The abundance of earthworms across habitats is highly variable depending on climatic and edaphic conditions, ecosystem type, and the degree to which the habitat has been altered, for example, by agriculture. Under otherwise suitable conditions, soil C concentration has been shown to be highly correlated with earthworm population density and biomass (Edwards, 1983; Hendrix et al., 1992). Earthworm density and biomass in a variety of habitats worldwide are presented in Table 25.14. Densities range from <10 to >2000 m^{-2}, with the highest values occurring in grasslands (especially fertilized pastures) and the lowest in acid or arid soils (coniferous or sclerophyllous forest). Typical densities from temperate deciduous or tropical forests and certain arable systems range from ca. 100 to 400 m^{-2}, depending on intensity and nature of disturbance. Earthworm biomass tends to track density, but biomass comparisons can be problematic due to different methods used by various investigators (Section 25.5.1). Because earthworm populations often show seasonal variation in abundance (especially in temperate regions), time of sampling also affects density and biomass estimates.

Within habitats, earthworms often show heterogeneous spatial distributions. "Single-tree-influence," spatial distributions of other controlling environmental factors (e.g., soil texture, moisture, or organic matter content), or intrinsic population characteristics (e.g., fecundity, body size, and dispersal ability) often result in aggregation or clumped distribution patterns of earthworm populations across landscapes. In addition, local habitat and feeding preferences of various earthworm species dictate their vertical distributions within the soil profile (Boetcher and Kalisz, 1991; Barois et al., 1999; Rossi et al., 2006). A categorization of earthworm life forms or functional types based on habitat and feeding ecology is presented in Table 25.15. These categories describe niche separation of earthworm species within a soil volume. Polyhumic, epigeic, and epiendogeic species utilize litter and organically enriched surface layers; poly-, meso-, and oligohumic endogeic species inhabit mineral soil

TABLE 25.14 Abundance and Biomass of Earthworms in Selected Habitats from Various Parts of the World

Habitat	Location	Collection Method	Earthworm Taxa	Abundance No. m^{-2}	Biomass g m^{-2} Fresh wt

TABLE 25.15   Ecological Strategies of Earthworms

Epigeic (litter dweller)—Mesophage; detritivore

Lives in and consumes litter; small size; uniformly pigmented

(e.g., *L. rubellus*, *Bimastos* spp., *Dendrobaena octaedra*, *Dendrobaena rubida*, *Eisenia foetida*, *Amynthas* spp.)

Endogeic (subsoil dweller)—Microphage; geophage; (epiendogeic or hypoendogeic; oligohumic, mesohumic, or polyhumic)

Lives in horizontal, branching burrows in organomineral layer; consumes soil; small to large in size; weakly pigmented

(e.g., *Aporrectodea caliginosa*, *Octolasion cyaneum*, *Diplocardia* spp., *Pontoscolex corethrurus*)

Anecic (topsoil dweller)—Macrophage; detritivore

Lives in deep vertical burrows, casting on surface; emerges at night to draw down organic matter (plant residue, etc.); large as adults (200–1100 mm); brown pigment anteriorly and dorsally

(e.g., *L. terrestris*, *Allolobophora longa*)

Broussssard, and P. Hendrix (eds.) Earthworms management in tropical agroecosystems. CABI Publishing, New York.

within the rhizosphere and beyond; and anecic species exploit both the surface litter as a source of food and the mineral soil as a refuge. Lee (1985) summarizes data showing that within a particular soil, commonly less than a half-dozen earthworm species are found. The species in a given earthworm association often effectively partition the soil volume according to the functional categories mentioned above. Furthermore, the activities of earthworms within these categories influence biogeochemical processes in various ways. For example, epigeic species facilitate the breakdown and mineralization of surface litter, whereas anecic species incorporate organic matter deeper into the soil profile and enhance aeration and water infiltration through burrow formation (Lee, 1985; Shipitalo and Le Bayon, 2004).

For management of earthworms in agroecosystems, Lee (1991, 1995) recommends that "target earthworm communities" consist of one or more anecic/epigeic species that make deep vertical burrows and that cast on the surface and bury residues, and one or more endogeic species that feed belowground on dead roots and organic matter and that make horizontal burrows. Diverse assemblages of earthworms may more effectively exploit soil resources and influence a wider array of processes, such as organic matter turnover, in addition to soil structural properties, than a single species.

25.6.4 Importance to Soil Processes

Where earthworms are abundant, they can exert significant influence on soil processes through effects on organic matter and nutrient cycling, and on soil structure. These topics are reviewed in Lee (1985), Hendrix (1995), Edwards and Bohlen (1996), Lavelle et al. (1999), Lavelle and Spain (2001), and Edwards (2004).

25.6.4.1 Organic Matter Dynamics and Nutrient Cycling

Effects of earthworms on organic matter and nutrient cycling are closely linked with the life form and feeding ecology of earthworms (Table 25.15). Epigeic species typically live in the O and upper A soil horizons where, through feeding and casting activities, they mix mineral soil and plant litter, fragment organic particles, inoculate them with microbes, and thereby accelerate organic matter decomposition rates. Anecic forms pull surface litter into their burrows, thus transporting organic material deeper into the soil profile. They cast on the soil surface, mixing organic and mineral particles in the litter layer. The activities of both epigeic and anecic earthworms produce "mull" soil horizons, defined as those in which organic matter is intimately incorporated into the upper mineral soil of a well-developed A horizon overlain with litter or humus layers <2 cm thick. The extreme case is termed "vermimull," in which the Ah horizon is granular and characterized by strong organomineral complexes consisting of earthworm casts (Green et al., 1993). Endogeic earthworms feed within the soil on organic matter and microbes associated with the rhizosphere or mineral soil. As mentioned previously, they are termed oligohumic, mesohumic, or polyhumic,

depending on the level of organic enrichment of their substrate. Casts and burrows of endogeic earthworms are also sites of increased microbial activity and organic matter decomposition, and the presence of these worms has been shown to positively influence the availability of nutrients in some soils (e.g., Callaham and Hendrix, 1997; Chapuis-Lardy et al., 2009). Mineralization of organic matter in earthworm casts and burrow linings produces zones of nutrient enrichment compared to bulk soil. These "hot spots" (the "drilosphere") are often sites of enhanced activity of plant roots and other soil biota (Beare et al., 1995; Lavelle and Spain, 2001). Indeed, most of the effects that earthworms have on soil organic matter and nutrient dynamics in ecosystems are mediated through their interactions with other soil biota and in particular soil microbiota, as earthworms have been shown to influence the size and composition of microbial communities (e.g., Svensson and Friberg, 2007; Pawlett et al., 2009), as well as the activity of microbial communities in terms of both total soil respiration and gaseous losses of nitrogen (Speratti et al., 2007).

25.6.4.2 Soil Structure

Soil structure is affected by earthworms principally through production of casts, which form stable aggregates upon and within the soil, and formation of burrows, which produce macropores that may increase water infiltration and aeration within the soil. Casts are produced by ingestion of mineral and organic particles, mixing, organic enrichment, and microbial stimulation in the gut, and egestion of the material as a slurry or as discrete pellets (depending on earthworm species), which harden into stable aggregates. Mechanisms of cast stabilization include organic bonding of particles by polymers secreted by earthworms and microbes, mechanical stabilization by plant fibers and fungal hyphae, and stabilization due to wetting and drying cycles and age-hardening/thixotrophic effects (Tomlin et al., 1995). Earthworm casts are usually enriched with plant available nutrients and thus may enhance soil fertility.

Earthworms create burrows of various sizes, depths, and orientations, depending on species and soil type. Burrows tend to be similar in diameter to that of the body, ranging from 1 to >10 mm diameter and constituting among the largest of soil pores (Lee, 1985; Tomlin et al., 1995; Shipitalo and Le Bayon, 2004). Geophagous species (Table 25.15) may form networks of variously oriented macropores, as the earthworms consume the soil and cast behind them as they burrow. Although such networks may form continuous pores for some depth, casting within the burrows may impede free water movement. Anecic earthworms may create vertical burrows that can form continuous macropores to depths of >1 m. Such burrows are often highly stable because their walls are lined with organic matter drawn in or secreted by earthworms, and they tend to have higher bulk density than surrounding soil. Continuous macropores resulting from earthworm burrowing may greatly enhance water infiltration by functioning as by-pass flow pathways through saturated soils (Lee, 1985; Tomlin et al., 1995; Shipitalo and Le Bayon, 2004). These pores may or may not be important in solute transport depending on antecedent soil water, nature of the solute, and exchange properties of the burrow linings (Edwards et al., 1990, 1993).

25.6.5 Methods

25.6.5.1 Earthworm Collection

Techniques for field sampling of earthworms are reviewed in Lee (1985) and Edwards and Bohlen (1996). Unless otherwise given, methodological details and specific reference citations can be found in these works. Collection techniques are passive, behavioral, and indirect (Table 25.16).

Hand digging and sorting, is the most commonly used and probably the most reliable method for quantitative sampling of earthworms. The technique involves digging pits of known dimensions (e.g., $25 \times 25 \times 25$ cm), breaking the soil by hand, and collecting all earthworms found. Often the collected specimens are immediately preserved in 70% ethanol or 5% formalin for later counting and identification (see Fender and McKey-Fender, 1990; Schwert, 1990, for details of preservation and preparation of specimens for identification).

Washing and sieving is an elaboration of hand sorting, in that the soil is dispersed in water (or a dispersing agent), poured through a sieve or nest of sieves, and the earthworms and cocoons hand picked from the sieve contents. Mechanized approaches to washing and sieving are described by Bouché and Beugnot (1972). Flotation of sieve contents in a high density solution, such as 1.16–1.20 SG $MgSO_4$, is an additional means of separating earthworms and other soil fauna from more dense soil particles.

A number of factors influence efficiency of hand sorting, including species and body size of earthworms (i.e., seasonal phenology and population demography), root density (especially in grasslands), soil type, and a "human factor," related to training of personnel and time spent on each sample (Schmidt, 2001a; Jiménez et al., 2006).

Several approaches have been taken to extracting earthworms from soil based on their behavioral response to certain stimuli. A number of chemical irritants have been used, including $HgCl_2$, $KMnO_4$, formalin and, more recently, mustard. Aqueous solutions of 0.165%–0.550% formalin have been used commonly and shown to be effective on *L. terrestris* when applied in three sequential doses of 18 L m^{-2} but formalin may be less effective on other species (Satchell, 1969; Callaham and Hendrix, 1997; Schmidt, 2001b). Aqueous extract of mustard has shown earthworm extraction efficiency similar to that of other chemical extractants and has come into favor because of its minimal effects on human health and low phytotoxicity compared to formalin (Gunn, 1992). Effectiveness of any chemical extractant varies with earthworm species and activity, temperature, soil porosity, and soil water content, saturated soils being less likely to transmit extractant solutions deep into the soil. Comparisons with hand sorting should be done before adopting chemical extraction techniques for quantitative sampling.

TABLE 25.16 Descriptions of Methods for Collecting Earthworms

Method	Description	Advantages	Disadvantages
Passive			
Hand sorting	Known volume of soil cut with spade or corer, broken and worms removed by hand	Simple, reliable in the field; low cost	Laborious; may not collect deep burrowing species, small earthworms and cocoons
Washing and sieving	Known volume of soil cut with spade or corer, soaked in dispersant/preservative, and washed through sieve(s) by hand or mechanical device	Higher recovery of cocoons and small individuals	Laborious; may not collect deep burrowing species
Flotation	Material from hand sorting or washing/sieving floated in high density solution (e.g., $MgSO_4$)	Separates earthworms from soil and plant debris; cocoons and small individuals collected	Laborious; may not collect deep burrowing species
Behavioral			
Chemical extraction	Soil saturated with chemical irritant (e.g., 0.2% formalin) causing earthworms to emerge onto soil surface	Simple; effective on deep burrowing anecic species	Not effective on all species, in all soils or under all conditions
Heat extraction	Soil blocks or cores suspended under heat lamps in water into which earthworms migrate	Effective on dense root mats	Not effective on all species; inconvenient for field use
Electrical extraction	Metal rods inserted into soil and connected to AC electrical source	Useful for selective or comparative sampling	Highly variable; not convenient in the field; dangerous
Mechanical vibration	Stake or rod inserted into soil and vibrated with bow or flat iron	Simple; useful for selective or comparative sampling	Not effective on all species
Trapping	Pitfall or baited traps placed in soil and sampled at desired intervals	Simple; useful for selective or comparative sampling	Not effective on all species
Mark–recapture	Individuals tagged, released, and population sampled at intervals	Useful for estimating population density, dispersal, and mortality	Laborious
Indirect			
Cast counting	Surface castings enumerated and identified	Simple	Not a quantitative estimate of population density

Sources: Summarized from Lee, K.E. 1985. Earthworms: Their ecology and relationships with soils and land use. Academic Press, Sydney, Australia. Edwards, C.A., and P.J. Bohlen. 1996. Biology and ecology of earthworms. 3rd edn. Chapman and Hall, New York.

The heat extraction method is a modification of that used for enchytraeids (see previous section). Soil cores or blocks are placed in pans of water, exposed to heat from overhead light-bulbs, and earthworms are collected from the water after several hours. This technique was more effective than hand sorting or formalin extraction on small earthworms in dense root mats (Satchell, 1969). As with hand sorting, it is not effective on deep burrowing, anecic species such as *L. terrestris*.

Mechanical vibration employs a rod or wooden stake driven into the soil, vibration for a few minutes with a bow or flat piece of metal (e.g., an automobile leaf spring), and collection of earthworms that emerge onto the soil surface. *Diplocardia mississippiensis* are routinely collected by fishermen in north Florida, with this method (termed "grunting") and Hendrix et al. (1994) used it for sampling *Diplocardia* populations in that region. Mitra et al. (2008) analyzed seismic signal characteristics of vibrations generated by the technique and found that numbers of worms emerging were positively correlated with signal strength. In general, vibration techniques may not be effective on many groups of earthworms, for example, lumbricids (Reynolds, 1973) and are probably not suited to quantitative measurements of population density. However, they may be useful for selective or comparative sampling of certain earthworm populations.

Electrical extraction of earthworms involves inserting metal rods into the soil, connecting them to a source of alternating current and collecting earthworms that come to the soil surface. Different voltages and amperages have been used with varying degrees of success; effectiveness of the technique is highly dependent on soil water content, electrolyte concentration, and temperature (Lee, 1985). As with mechanical vibration, the soil volume sampled is not known and therefore this method has been considered best suited for qualitative or comparative sampling. However, a comparative analysis by Schmidt (2001b) found that the "octet method" of Thielemann (1986) extracted higher earthworm numbers than the formalin method and gave community size and species composition estimates comparable to that of the hand sorting method. Schmidt (2001b) concluded that the octet method may be reliable and especially useful in situations requiring minimal soil disturbance. It must be cautioned that all electrical methods are potentially very dangerous and should only be used with extreme care.

Two earthworm-trapping techniques have been described. Pitfall traps (open-top containers buried level with the soil surface and containing a fixative solution, such as picric acid; see Section 25.4) may be useful for sampling surface-active species in diurnal or seasonal studies (Callaham et al., 2003b). Arrays of

traps are installed and sampled at 12, 24 h, or longer intervals. Baited traps, such as perforated clay pots containing manure or other attractants and inserted into the soil may also be useful for collecting certain species. As with other behavioral methods, trapping is probably highly selective and best suited for qualitative or comparative sampling.

Mark, release, and recapture techniques have been widely used to study population dynamics of animals, including earthworms. Large numbers of individuals of desired species are collected, marked (e.g., with brands or nontoxic dyes), and released into the population of interest. Sampling over time and distance from the target site, and enumeration of tagged relative to untagged individuals, yields information on dispersal, mortality, and population density. Dyes (Mazaud and Bouché, 1980) and radioisotopes (Bastardie et al., 2003) have been employed to mark earthworms. González et al. (2006) recently evaluated the use of a fluorescent elastomer injected into *Pontoscolex corethrurus* and were able to trace the marker for four months in populations incubated in field enclosures. Likewise, other studies (Butt and Lowe, 2006; Butt et al., 2009) showed that these elastomers did not affect the growth rates or cocoon production in *L. terrestris* and could be detected in the coelomic cavities of seven different earthworm species for up to 2 years (but sometimes was detected only after dissection). For earthworm species that cast on the soil surface, such as *Aporrectodea longa*, numbers and identity of castings may be a useful index of population activity. Because casting is dependent on soil temperature and moisture, this technique is highly variable and not a quantitative estimate of population density.

In addition to measurements of earthworm density (i.e., numbers per unit area), it is desirable to have estimates of earthworm biomass in most quantitative studies. Specimens from field collections contain varying amounts of gut contents that affect body mass measurements and therefore it is necessary to remove this material either by allowing live earthworms to void their guts (e.g., overnight in moist paper towels) or by dissecting and removing gut contents from preserved specimens. "Fresh weight" or "wet weight" measurements face two further problems: First, earthworms under field conditions contain varying amounts of water, and second, preserved specimens lose differing amounts of fresh mass in different preservative fluids (e.g., profuse mucus secretions in formalin; Lee, 1985). These factors must be considered in comparative studies across sites or seasons, or when different preservations techniques are used. For most purposes, it is best to convert live weight into dry weight, which may be accomplished by directly drying gut-voided specimens (e.g., freeze drying) or by using allometric relationships or regressions that relate body length or wet weight to dry weight (Lee, 1985; Hale et al., 2004), or oven dried weight to ash-free dry weight (Callaham et al., 2003a). Isotopic studies of earthworm feeding ecology require measurement of carbon mass, while also maintaining specimens for taxonomic identification. Live specimens can be killed instantly in boiling water and divided into a posterior half for gut clearance and freeze drying for chemical analysis, and an anterior half for preservation in formalin or ethanol for morphological taxonomic study (e.g., Hendrix et al., 1999).

Finally, for those interested in molecular techniques for evaluating the presence of earthworms in environmental samples, new techniques are rapidly being developed for detection of earthworm DNA or other proteins, and these hold great promise for rapid analysis of samples with high resolution information for diversity of organisms in samples. These techniques include using whole soil DNA extractions followed by sequencing and comparison against clone libraries (as in Wu et al., 2009), as well as more specific applications such as those in Juen and Traugott (2006) where DNA was used to identify the different prey items (including earthworms) in the gut of a soil predator.

In summary, digging and hand sorting or washing are probably the most reliable means of sampling earthworms. However, no single method will be adequate to sample earthworm populations in all situations. Combinations of methods will probably achieve reasonable results. For example, formalin or mustard solution can be applied to the bottom of pits previously excavated for hand sorting, to extract deep burrowing anecic forms not sampled by digging (Edwards and Bohlen, 1996). Combinations of various methods may be useful in other situations.

25.6.5.2 Identification

Many earthworm species in the family Lumbricidae can be identified from external body characteristics if the specimens are sexually mature. Taxonomic keys by Reynolds (1977), Schwert (1990), and Sims and Gerard (1999) are useful for the common lumbricids found worldwide. Reynolds (1977) also includes a key to North American Sparganophilidae, a limicolous or semi-aquatic group.

Most earthworms other than the Lumbricidae require dissection for accurate taxonomic identification. Knowledge of position and characteristics of sexual organs, the gut and associated glands, and other structures is required. The procedures must be done carefully and require a degree of skill and practice. At the family level, several keys are available: Jamieson (1988, 2000) contain a key and diagrammatic comparison of characteristic internal structures of most families, including the Megascolecidae of Australia; Edwards and Bohlen (1996) review major characteristics of the families; Sims and Gerard (1999) provide keys and species descriptions for seven families found in Great Britain; Fender and McKey-Fender (1990) give keys to the families of North America and the genera of Megascolecidae from western North America; James (1990) provides a key to the genus *Diplocardia*, a group of megascolecids found mostly in eastern North America, including, Mexico and the Caribbean. Righi (1971) describes the Glossoscolecidae in Central and South America. Many of the works cited in Gates (1982) include keys and species descriptions for families and genera found in North and Central America.

The taxonomy and systematics of earthworms, as with many other taxa, is currently undergoing considerable revision as advances in molecular biology prompt reevaluation of accepted

phylogenies and taxonomic relationships (e.g., Jamieson et al., 2002; Marotta et al., 2008). Although these approaches have great promise for providing clarity to taxonomic problems that have plagued earthworm nomenclature for decades, it is clear that much work remains and that even with DNA-based approaches, some controversy will remain (see Chang et al., 2008). Internet resources provide the best means of keeping track of these revisions and the development of new taxonomic keys (e.g., http://zipcodezoo.com/animals, http://www.discoverlife.org, http://species.wikimedia.org/wiki/Main_Page, and http://tolweb.org/tree).

26.1 Phosphorus and Sulfur in Soil

Emmanuel Frossard

Else K. Bünemann

Astrid Oberson

Jan Jansa

Michael A. Kertesz

26.1.1 Introduction

26.1.1.1 Phosphorus and Sulfur as Indispensable Elements for Life

Both phosphorus (P) and sulfur (S) are indispensable for living organisms. Phosphorus is contained in DNA and RNA and as such is important with respect to storing and reading genetic information. Phosphorus is also found in ATP and its derivatives, and is vital for energy storage and transfer in the cell. Finally, phosphorus is present in phospholipids that are important components of cell membranes.

Sulfur is part of some amino acids (cysteine and methionine) and of proteins. The presence of cysteine in proteins allows the formation of disulfide bonds, which are involved in the tertiary structure of proteins. Sulfur plays an important role in enzymes as a metal-binding element. It is present in the coenzyme A that is a key intermediate in lipid synthesis and in the vitamins biotin and thiamin. Sulfur is also contained in specific molecules such as glutathione that play an important role for the transport and detoxification of metals or pesticides in the cell.

Given their importance for plants, phosphorus and sulfur are widely used as fertilizers in agro-ecosystems. However, mineable reserves of phosphorus are finite and might be sufficient for little more than 100 years (Cordell et al., 2009). Thereafter, phosphorus fertilizer prices will increase strongly. For sulfur, the reserves are probably much larger. The sulfur removed from fuel supplies and smoke stacks provides an extensive reserve.

26.1.1.2 The Cycles of Phosphorus and Sulfur in Soils

The concentrations of total phosphorus and sulfur in soil range between less than 100 and more than 1000 mg kg^{-1}. Young soils located on phosphorus- or sulfur-rich parent material present higher total phosphorus and sulfur contents (>1000 mg kg^{-1}) while strongly weathered soils developed on a parent material with low phosphorus and sulfur contents can have very low total phosphorus and sulfur contents (<100 mg kg^{-1}).

Most of the soil phosphorus is present as phosphate. Soils contain between 20% and 80% of the total phosphorus in organic forms. The following forms of organic phosphorus can be found (in the order of decreasing abundance): monoester phosphates, such as phytate (*myo*-inositol hexakisphosphate), with the

general formula $R-O-PO_3^{2-}$ (R being an organic moiety); diester phosphates, such as nucleic acids, with the general formula $R-O-(PO_2^-)-O-R'$ (R and R′ being two organic moieties); and phosphonates with the general formula $R-C-PO_3^{2-}$ (R being an organic moiety). Finally, a small proportion of soil phosphorus can be found as pyro- and polyphosphate $((PO_3)_n)$, which are not organic molecules but can be of biological origin (Bünemann and Condron, 2007).

All the oxidation states of sulfur can be observed in soil depending on its redox status. In aerobic soils, 90% of the total sulfur is present in organic forms. The most important organic forms are in a strongly reduced state (e.g., sulfide and thiophene), in an intermediate oxidation state (sulfoxide and sulfonate), and in a strongly oxidized state (ester sulfate) (Solomon et al., 2003).

Both elements can enter the soil through rock weathering, atmospheric inputs, erosion, and inorganic and organic fertilizers (Figure 26.1). Whereas phosphorus inputs from the atmosphere are limited, sulfur inputs in gaseous form can be significant in volcanic regions and in regions with high rates of atmospheric pollution. Since air pollution control programs have been implemented in Europe and North America, the input of sulfur from the atmosphere has greatly declined.

Both elements leave the soil through the exportation of harvested products from agricultural fields, erosion, runoff, and leaching. A major difference between the phosphorus and sulfur cycles is the sometimes important loss of sulfur from soils in gaseous forms (e.g., as hydrogen sulfide or sulfur dioxide) whereas gaseous losses of phosphorus (e.g., as phosphine) are negligible.

Phosphorus in the form of orthophosphate (HPO_4^{2-} and $H_2PO_4^-$) and sulfur in the form of sulfate (SO_4^{2-}) can react with soil particles through sorption/desorption and precipitation/dissolution mechanisms. These species can also be taken up by plants and microorganisms and incorporated into stable organic compounds. Conversely, microbial activity can also trigger the release of phosphorus and sulfur compounds to the soil solution.

In most cases, abiotic and biotic reactions maintain the concentrations of sulfate and phosphate in the soil solution at a low level. This is why plants and microorganisms have developed efficient mechanisms to acquire these elements.

This short review of the phosphorus and sulfur cycles in soils covers some recent developments in analytical approaches to study pools and fluxes of these elements in soils (Section 26.1.2). Then we present the most important biotic (Section 26.1.3) reactions that these elements undergo. Finally, the factors and processes controlling phosphorus and sulfur forms and dynamics are presented for two exemplary soil systems (Section 26.1.4). The abiotic reactions that these elements undergo are not discussed here as they are presented elsewhere in this handbook. For more extensive reviews on these elements, the reader is referred to Sims and Sharpley (2005), Bünemann and Condron (2007), and Kertesz et al. (2007).

26.1.2 Methods of Investigation

26.1.2.1 Chemical/Biochemical Extractions

Chemical extractions have been extensively used to estimate the amount of phosphorus and sulfur present in different forms in soils. Dilute aqueous solutions (water or $CaCl_2$) can be used to extract the amount of plant-available phosphorus and sulfur. Extracting soils with resin strips or iron oxide paper allows an estimation of the fraction of phosphate that is sorbed and can be released to the solution. Plant extractable sulfur can be assessed by extraction with orthophosphate or with a resin.

Sequential extraction schemes have been developed for assessing phosphorus and sulfur forms in soils. For phosphorus (Hedley et al., 1982), the rapidly plant-available form is first removed from the soil with a resin. The sediment is then extracted with $NaHCO_3$ and then with NaOH. These two alkaline extractants solubilize phosphorus bound to aluminum and iron oxides and organic forms of phosphorus. The sediment is then extracted with HCl to dissolve phosphorus bound to calcium. Finally, an acid digestion can be conducted on the sediment to extract the residual phosphorus. For sulfur, a commonly used sequential extraction (Freney et al., 1975) begins with an extraction with orthophosphate, followed by

a digestion of the sediment with hydriodic acid. Ester sulfates are converted to hydrogen sulfide during this digestion while the sulfur remaining in the sediment is considered to be directly bound to carbon. The sediment can then be treated with Raney Ni to separate reducible sulfur (S in amino acids) from nonreducible sulfur forms. Sequential extractions give fair information on phosphorus and sulfur forms, but the amounts of extracted elements depend strongly on the chemical extractant that is used, and some artifacts can occur during the extraction (e.g., formation of new compounds during the extraction).

The fraction of phosphorus and sulfur stored in the microbial biomass can be estimated by comparing the amount of element extracted from a soil sample that has been fumigated with an organic solvent (e.g., chloroform, hexanol, and toluene) to that extracted from a nonfumigated sample (Saggar et al., 1981; Hedley and Stewart, 1982). The fumigation causes the lysis of microbial cells, releasing elements stored in the microbial biomass into the soil solution. This approach poses two types of problems: first, only a fraction of the microbially held element is released, and second, a fraction of the released phosphate is quickly sorbed onto soil surfaces. Whereas the correction for phosphate sorption is straightforward, it is more difficult to

correct for the incomplete extraction of the microbial phosphorus and sulfur (Oberson and Joner, 2005).

Recently, enzymatic approaches have been proposed to assess the availability and speciation of phosphorus and sulfur in organic forms in soils and solution. Hydrolases of the phosphorus or sulfur cycles are added in large amounts to soil extracts or soil suspensions, and the fraction of element released during the experiment is measured. On the one hand, the use of an enzyme cocktail able to hydrolyze a larger number of organic phosphorus compounds yields information on the total amount of phosphate that can potentially be released from organic compounds. On the other hand, the use of a specific enzyme will give precise information on the proportion of the specific form of organic phosphorus accessible to the enzyme. These enzymatic approaches have a lot of potential but need to be standardized before they can deliver results that can be correctly interpreted (Bünemann, 2008).

26.1.2.2 Spectroscopic Approaches

Two spectroscopic methods are gaining importance for the study of phosphorus and sulfur in soils: nuclear magnetic resonance (NMR) and x-ray absorption spectroscopy.

NMR is used to characterize the close chemical environment of nuclei that possess an odd number of protons and neutrons such as the ^{31}P nucleus. Two types of NMR experiments can be conducted on soils: liquid-state ^{31}P NMR and solid-state ^{31}P NMR. Liquid-state ^{31}P NMR experiments are usually conducted on NaOH–EDTA soil extracts. Earlier work had shown that this technique could allow quantitatively assessing the abundance of phosphonates, orthophosphate, monoester phosphates, diester phosphates, pyrophosphates, and polyphosphates in NaOH extracts (Condron et al., 1990); but assigning peaks to specific compounds was problematic. More recently, Turner et al. (2003a, 2003b) and Turner and Richardson (2004) proposed approaches to assign these peaks to DNA, RNA, phosphatidyl choline, phosphatidyl serine, phosphatidyl ethanolamine, polyphosphates, *scyllo*-inositol phosphates, and *myo*-inositol phosphates. Smernik and Dougherty (2007) however stress the need to carefully spike the soil extracts to obtain relevant concentrations of *myo*-inositol phosphates in soil extracts and to avoid artifacts due to changes in pH and ionic strength. This is important as *myo*-inositol phosphates, such as phytate, are considered to be the dominant pool of organic phosphorus in soils.

Soil phosphorus forms can also be studied with solid-state ^{31}P NMR. Experiments can be conducted in the cross-polarization (CP) or in the direct-polarization (DP) mode. Experiments done in CP allow the observation of ^{31}P nuclei located in the close vicinity of ^{1}H whereas experiments done in DP mode theoretically allow the observation of all ^{31}P nuclei. The interest of solid-state ^{31}P NMR is to obtain information on mineral and organic P forms present in a soil without chemical extraction. Using solid-state ^{31}P NMR, McDowell et al. (2002) report the presence of various aluminum and calcium phosphates (berlinite, wavellite, variscite, monetite, dicalcium phosphate dihydrate, hydroxyapatite,

and octocalcium phosphate) in the upper horizon of three soils containing high total P contents (>1400 mg P kg^{-1}). However, the use of this technique in soil faces a number of problems: the total phosphorus content is usually lower than 1000 mg P kg^{-1}, phosphorus is distributed in a large number of forms, and soils usually contain large amounts of iron and manganese, which hinder the observation of ^{31}P nuclei by NMR. Dougherty et al. (2005) using the technique of spin counting showed that only 9% of the total P could be observed by CP solid-state ^{31}P NMR and 22% by DP. They attributed this poor "observability" to the presence of Fe in the close vicinity of P nuclei. They conclude their paper by stating that considerable methodological work must still be carried out, considering "observability," chemical shift anisotropy, and relaxation rates, in order to obtain relevant information from solid-state NMR ^{31}P experiments.

The use of x-ray absorption spectroscopy for the study of soil phosphorus and sulfur developed during the last two decades. Most work on phosphorus and sulfur has been carried out with x-ray absorption near edge structure (XANES). Hesterberg et al. (1999) obtained phosphorus K edge XANES spectra from a number of mineral phosphorus forms, including phosphate bound to Fe, and showed the presence of calcium phosphate in a soil. Using phosphorus K edge XANES and sequential extraction, Beauchemin et al. (2003) showed the presence of phosphate adsorbed on iron and aluminum oxides and of calcium phosphates (hydroxyapatite and octocalcium P) in phosphorus-rich soils. Sato et al. (2005) observed phosphate bound to iron oxides in a forest soil and poorly crystallized calcium phosphates (dibasic calcium phosphate, amorphous calcium phosphate, and tricalcium phosphate) in soils that had received organic manures. Lombi et al. (2006) studied the distribution of phosphorus at the nanoscale in a highly calcareous soil with nano x-ray fluorescence and nano XANES, showing that phosphorus was heterogeneously distributed in this soil and that it was associated with calcium rather than iron. A big advantage of XANES compared to NMR is its ability to detect mineral phosphate forms bound to iron. A disadvantage of phosphorus K edge XANES is the lack of sensitivity of this technique for organic forms of phosphorus (Toor et al., 2006). A recent report from Kruse et al. (2009) shows however that the phosphorus $L_{2,3}$ edge XANES is richer in spectral features than the K edge XANES and therefore should allow for a more precise analysis of organic and mineral P compounds in soil. Finally, as in the case of solid-state ^{31}P NMR, XANES yields good results for soils with quite a high phosphorus content (>1000 mg P kg^{-1}).

The application of sulfur K edge XANES led to a significant leap forward in our knowledge of sulfur speciation in soils. Morra et al. (1997) showed that it was possible to differentiate sulfur forms in humic and fulvic acids according to their oxidation state. Solomon et al. (2003) could quantify with this technique the amount of sulfur present in a strongly reduced state (e.g., sulfide and thiophene), in an intermediate oxidation state (sulfoxide and sulfonate), and in a strongly oxidized state (ester sulfate) in the humic substances extracted from particle size separates of different soils. Although the sulfur K edge XANES spectra of nonextracted particle size separates could not be

quantitatively analyzed due to the high background, they were very similar to the spectra obtained from their humic extracts. The authors concluded that sulfur K edge XANES of humic substances represents adequately organic sulfur forms in total soil. Prietzel et al. (2007) on the contrary observed significant differences between the sulfur forms measured by XANES on humic and fulvic extracts, on size separates and on bulk soil samples. They suggest that sulfur speciation might have changed during the preparation of the humic extracts and that ester sulfate might be enriched in the clay fraction of soils. Prietzel et al. (2008) showed that sulfur K edge XANES could be used to distinguish adsorbed from precipitated sulfate in bulk soils and in microsites in a wide range of sulfate-rich soils.

26.1.2.3 Stable and Radioactive Isotopes
